Certificates were read for the first time in favour of Messrs. John Burke Fairley, 2, Sidney Villas, Lower Eglinton Road, Shooter's Hill; A. Alexander Ramsay, Auckland, New Zealand; C. Heinrich Trinks, 117, King Henry's Road, N.W.

The following were elected Fellows of the Society:—Messrs. John Alexander, Charles Bradshaw, Lewis Edmunds, William Humphrey Gibson, Joseph Henry Maiden, Henry Alexander Miers, M.A., Frank Mousley, James H. Rymer Paterson, George Woodyatt Procter, Herbert W. Seely.

The following papers were read:—

48. "*Chlorofumaric and Chloromaleic Acids and their Magnetic Rotatory Powers.*" By W. H. PERKIN, Ph.D., F.R.S.

The author has further studied the action of phosphorus pentachloride on tartaric acid, first examined by Mr. Duppa and himself in 1861. The main product is the chloride of *chlorofumaric acid*, not chloromaleic chloride as was formerly supposed. In the paper, the properties of the chloride are described, and also those of the acid and of its acid potassium, ammonium, and ethylic salts. On treatment with ammonia, the ethylic salt is first converted into the ethylic salt of chlorofumaramic acid,—

a substance already described by Claus and Voeller as a maleic compound; on further treatment with ammonia, amidofumaramide is produced; this crystallises in pale yellow needles, and decomposes when heated, no definite fusing point being observable. Claus and Voeller, operating in the same manner, have, however, obtained a substance which, although of the same composition, crystallises in colourless scales, melting at 122°.

On heating a mixture of chlorofumaric acid and chlorofumaric chloride, chloromaleic anhydride is obtained; this substance is dimorphous, being obtainable in hard crystals melting at 34.5°, and as a solid which melts just below 0°. Chloromaleic acid and a number of its salts are fully described in the paper; like the maleates, the chloromaleates yield a brown-red colouration with ferric salts, while the chlorofumarates, like the fumarates, afford a buff precipitate with ferric salts. The magnetic rotatory powers of a number of the compounds described are recorded in the paper.

49. "*Combustion by means of Chromic Anhydride.*" By C. F. CROSS and E. J. BEVAN.

Ladenburg in 1865 described a method of ultimate analysis of carbon compounds, consisting in heating with iodic acid and sulphuric acid in sealed tubes; the oxidation was found complete for a satisfactory variety of substances, and the experimental numbers obtained showed the process to be available as a laboratory method of estimating carbon and hydrogen.

The authors have investigated the action of chromic anhydride in presence of sulphuric acid on carbon compounds. Ladenburg mentions this "combustion mixture," but regards it as unavailable for quantitative determinations on account of the CrO_3 decomposing with evolution of oxygen. This, however, is shown by the author's experiments to take place to so small an extent under the conditions as to time and temperature of a combustion, that it may be neglected.

The action of the mixture has been investigated under

atmospheric pressure in vessels connected with a gas collecting and measuring apparatus. The carbon of the celluloses and carbohydrates is entirely converted into gaseous products. Some typical benzenoid compounds have also been investigated, and the results indicate that complete oxidation may be effected. The monobasic acids of the fatty series on the other hand are not completely resolved, and the results are consequently variable. Amide and imide nitrogen prevent complete oxidation; one of the causes probably being that urea is not attacked by the mixture. Compounds containing negative radicles, such as Cl, Br, S, and NO_2 , have not been investigated.

DISCUSSION.

Mr. A. H. ALLEN said that he had been in the habit for years of using chromic anhydride for oxidising carbon in steel, but he had found that some carbon dioxide was always evolved when pure sulphuric acid and the commercial anhydride were used; he therefore prepared the solution of the anhydride from fused lead chromate and sulphuric acid.

50. "*Metaxylenesulphonic Acids.*" By G. T. MOODY, D.Sc.

According to Jacobsen, metaxylene yields two sulphonic acids; the 1 : 3 : 4 modification is the chief product, the 1 : 2 : 3 modification being also formed, and in larger quantity when the temperature during sulphonation is low. The primary object the author had in view was to ascertain if the 1 : 2 : 3 acid was convertible by isomeric change into the isomeride, the investigation being one of a series which are being carried on in the Central Institution Laboratory for reasons briefly stated by Dr. Armstrong in Abstract No. 99, 1887.

The author arrives at the conclusion that the contradictory results obtained by Jacobsen, Remsen, and others on sulphonating metaxylene, are to be explained by the fact that in their investigations they did not use a pure hydrocarbon. Metaxylenesulphonic acid, obtained by sulphonating crude metaxylene, may be freed from paraxylenesulphonic acid and other impurities by repeatedly crystallising it from sulphuric acid diluted with one-third its weight of water in the manner described by Jacobsen, who, however, clearly did not carry the purification far enough. The pure sodium salt differs greatly from the description of it given by Jacobsen (*Berichte*, 1878, 17). It crystallises in beautiful tables belonging, in all probability, to the anorthic system, and contains one molecule of water of crystallisation. When hydrolysed, the pure sodium salt yields a hydrocarbon which on sulphonation with chlorosulphonic or sulphuric acid, gives *only one* sulphonic acid, the sulphonamide prepared from which melts at 137°.

Jacobsen's sulphonamide, melting at 95–96°, is not a derivative of metaxylene at all, but a mixture containing a considerable quantity of paraxylenesulphonamide; the solid xyleneol obtained from it by Jacobsen being identical with paraxylenol, which he describes in the same paper.

Dibromometaxylenesulphonic acid, on reduction with zinc-dust and sodium hydroxide, yields a sulphonic acid, the barium salt of which crystallises in large prisms, the sulphochloride in prisms melting at 39°, and the sulphonamide in slender brittle needles, melting at 113°. Jacobsen and Weinberg obtained this sulphonamide in an impure condition (*Berichte*, 1878, 1534), and regarded it as identical with that melting at 95–96° obtained by Jacobsen on sulphonating "metaxylene" with sulphuric acid.

If the sulphonic acid giving the sulphonamide, melting at 113°, be heated at 100°, isomeric change readily occurs, and the acid corresponding to the amide, melting at 137°, is formed.

The author proposes to closely study the derivatives of the acid yielding the amide, melting at 113°.

51. "*The Formation of Isomeric Toluenesulphonic Acids.*" By HUGH GORDON, B.A.

The object which the author has had in view was

similar to that by which the author of the previous communication was guided. It is well known that when toluene is sulphonated at low temperatures a large proportion of ortho-acid is obtained, whereas if sulphonation be effected at a temperature near the boiling-point of toluene, the para-acid is the almost exclusive product; it is obviously important, if possible, to determine whether or no the para-acid is formed from the ortho-acid by simple isomeric change. The author finds that tolueneortho-sulphonic acid (hydrated) is not affected by heating at 100°, but by somewhat prolonged heating at 140–150° it is converted into the para-acid; and inasmuch as this temperature is far above that at which toluene boils, it appears improbable that the ortho-acid becomes hydrolysed, and that the para-acid is formed by re-sulphonation of the toluene at a high temperature. The results as yet obtained are regarded, however, as incomplete, an extended investigation of the behaviour of the various sulphonic acids, both of toluene and of toluene-derivatives, being in progress.

52. "A New Method for the Preparation of Mixed Tertiary Phosphines." By NORMAN COLLIE, Ph.D.

The author has already called attention to the way in which when heated compound phosphonium chlorides decompose into the chlorhydride of the tertiary phosphine and an olefine. He has since used this as a method for the preparation of mixed tertiary phosphines. Triethylphosphine has been united with methyl, propyl, amyl, and benzyl chlorides respectively; all these compound phosphonium chlorides, when heated, decompose in a manner similar to the tetrethylphosphonium chloride, yielding ethylene and chlorhydrides of the tertiary phosphines.

The tertiary phosphines were prepared from the chlorhydride by the action of caustic soda. In this manner the following phosphines have been obtained:—Methyldiethylphosphine, dimethylethylphosphine, propyldiethylphosphine, amyldiethylphosphine, benzyldiethylphosphine, and dibenzylethylphosphine.

53. "Some Interactions of the Halogen Hydrides." By G. H. BAILEY and G. J. FOWLER.

The authors have found that when phosphorus pentoxide is exposed to hydrogen chloride gas at ordinary temperatures, large quantities of the gas are taken up by it, amounting to nearly a quarter of a litre per grm. of the pentoxide, the gas and the pentoxide interacting chemically: $2P_2O_5 + 3HCl = POCl_3 + 3HPO_3$.

A similar interaction occurs with hydrogen bromide, but none with hydrogen iodide. They have also observed that though hydrogen chloride has no action on mercury, yet if mixed with oxygen it readily attacks the mercury, forming an oxychloride, $Hg_2OCl_2 \cdot HgO$, action taking place even in the dark. With hydrogen, bromide, gas, and oxygen the interaction is more rapid, but whereas in the case of the chloride the whole of the hydrogen is oxidised to water, in the case of the bromide a large proportion remains uncombined. Hydrogen iodide gas forms with mercury mercurous iodide or mercuric iodide according as the mercury or the iodide is in excess.

54. "Remarks on the Paper of Drs. Japp and Klingemann on the Constitution of certain so-called Mixed Azo-Compounds." By Prof. VICTOR MEYER.

From a note on page 523 of the above-named article (*Chem. Soc. Trans.*, 1888), I see that Messrs. Japp and Klingemann regard my "Nachschrift," in the *Bericht* (1888, p. 18), as a claim of priority on my part. On re-perusing the article I see that the wording, quite unintentionally on my part, permits of such a reading. I therefore hasten to explain that the results there referred to were arrived at by Messrs. Japp and Klingemann and myself, independently, and that without doubt they obtained theirs ere I did mine. Nothing is further from my thoughts than the desire to detract from the merits of these workers, especially in a field which they have enlarged by such valuable and successful investigations.

55. "The Action of Potassium on Tetraalkylammonium Iodides." By C. M. THOMPSON and J. T. CUNDALL.

According to Weyl, if potassium in solution in liquid ammonia act on ammonium chloride, ammonium is produced and dissolves in the ammonia, forming a blue solution; this statement lacks confirmation, and has even been contradicted. In the hope of obtaining more decisive results, the authors have substituted tetramethyl- and phenyltrimethyl-ammonium iodide for ammonium chloride, but unsuccessfully. The greater part of the former was unchanged, a portion only being acted on by the potassium giving potassium iodide, ethane, and triethylamine; from the latter, potassium iodide, dimethylaniline, and trimethylamine were obtained.

56. "The Solubility of Isomeric Organic Compounds in Relation to their Fusibility." By THOMAS CARNELLEY, D.Sc., and ANDREW THOMSON, D.Sc., M.A., University College, Dundee.

Seven years ago (*Phil. Mag.*, [5], xiii., 180) one of the authors showed that the fusibility and solubility of isomeric compounds were very closely related to one another, so that of two or more isomeric bodies, that dissolves the most easily which has the lowest melting-point, and in which the atomic arrangement is the least symmetrical. At that time the investigation had included only a comparatively small number (58) of compounds. The authors have now extended the investigation, so as to include all isomeric sets of carbon compounds whatever. Their data have been obtained partly from literature and partly as the results of their own determinations. The following are their general conclusions:—

(1.) For any series of isomeric carbon compounds the order of solubility is the same as the order of fusibility, *i.e.*, the most fusible compound is also the most soluble. This rule has been applied in 1778 cases, of which 1755 accord with the rule, including all kinds of isomers, from the most simple to the most complicated. There are only 23 exceptions, and a large proportion of these is of a very doubtful character.

(2.) The order of solubility of the corresponding salts of any series of isomeric organic acids is the same as that of the acids themselves, *i.e.*, the salts of the more soluble and more fusible acids are also more easily soluble than the corresponding salts of the less soluble and less fusible acids; and if fusible more easily fusible, but the melting-points of most organic salts cannot be determined because they decompose before fusion. To this rule there are five exceptions out of 143 cases in which the rule can be applied, and as regards at least three of these it is very doubtful whether they are real exceptions.

(3.) The order of solubility of two or more isomeric compounds is independent of the nature of the solvent. This rule can be applied in no less than 666 cases, and among these there is not a single exception. The truth of the rule has also been proved more particularly in the case of meta- and para-nitraniline, the solubility of each of which in 13 different solvents has been carefully determined.

(4.) The ratio of the solubility of two isomers in any solvent is constant, and is independent of the nature of the solvent; this has been proved as yet only in the case of the meta- and para-nitranilines in respect of 13 different and very varied solvents.

The extremely close and intimate relation of solubility to fusibility, however, is proved not only by the very large number of cases of isomeric compounds which the authors have examined (nearly 2000), but also by the relative fusibility and solubility of the various allotropic modifications of the same element (*e.g.*, P, S (?), Se), and of mixtures of organic compounds (*e.g.*, solid paraffins), and of inorganic salts (*e.g.*, sodium and potassium nitrates), in all of which it is pointed out that the order of solubility is the same as the order of fusibility, and that this order is independent of the nature of the solvent.

The curve of the solubility of mixtures of sodium and potassium nitrates in various proportions is very striking.

Starting with pure sodium nitrate, the solubility increases and the curve rapidly falls as the percentage of NaNO_3 diminishes and that of KNO_3 increases, until the proportion of the latter amounts to about 20 per cent; the solubility then remains constant and the curve becomes a horizontal line until the proportion of the potassium salt reaches about 40 per cent, after which the solubility diminishes and the curve rapidly rises until pure KNO_3 is reached. The curve of fusibility falls rapidly from pure NaNO_3 , until the latter amounts to 50 per cent, after which it remains constant until the KNO_3 equals 60 per cent, and then rises rapidly until pure KNO_3 is reached.

57. "Notes on some Compounds of Chromium." By SYDNEY LUPTON, M.A.

The determination of the atomic weight of chromium has occupied the attention of many chemists, but from a variety of causes the results obtained are far from satisfactory. In some cases single experiments are relied on, and in others proper attention has not been paid to the solubility of silver chloride in solutions of chromic chloride, the great difficulty of drying chromic sulphate without decomposition and of completely decomposing it by heat, the liability of barium chromate to carry down other salts, or to be carried down by barium sulphate. Hence the true atomic weight cannot be considered to be determined to within about 1 per cent. In fact Clarke, placing apparently great reliance on a single experiment of Siewert's, takes $\text{Cr} = 52.01$; while Meyer and Seubert, giving greater weight to the experiments of Berlin, assume $\text{Cr} = 52.45$, which is practically the value preferred by Fresenius.

The following experiments were made with the object of suggesting a method for the determination of the atomic weight of chromium free from the defects inherent in all the methods which have hitherto been used. Incidentally a few old results have been either confirmed or rendered doubtful.

Potassium Dichromate.—The density of this salt was found by Thomson to be 1.98, which is copied into such authorities as Wurtz's "Dictionnaire" and Biedermann's "Chemiker Kalender," 1884. Karsten found 2.6; Miller's "Elements" gives 2.62; Schröder found about 2.7. The density of some small crystals of the twice re-crystallised salt was determined in benzene, the air being removed by a small hand-pump; it was found to be (i.) 2.69, (ii.) 2.67.

Ammonium Dichromate.—The density is given by Clarke as 2.151. Three experiments in benzene, the air being removed by a small pump, gave (i.) 2.16, (ii.) 2.18, (iii.) 2.75, and one in chloroform (iv.), 2.18

100 grms. of water dissolve—

At 7°	0°	about 23 grms. of the salt;	at 60°	about 82 grms.
" 10°	" 24	"	94	" 115 "
" 16°	" 28	"	107	" 173 "
" 18°	" 33	"		

The solution boils at 107° C.; its density is 1.12 at 10°, and 1.158 at 18° C.

The finely-powdered salt is easily dried at 110° in the air-bath.

Darby states (*Four. Chem. Soc.*, i., 20) that ammonium dichromate decomposes suddenly when heated to 200°. A small quantity of the dry powdered salt was heated in a thin test-tube, with a thermometer inside placed in a paraffin bath. Sudden decomposition took place at (i.) 228° C.; (ii.), 230° C.

Since the composition of the salt has been placed beyond doubt by Siewert (*Fahresb.*, 1862, 148), the ignition of ammonium dichromate and the determination of the chromic oxide left seems in theory to afford an unexceptionable method of determining the atomic weight; but the difficulty of avoiding loss of oxide by the sudden rush of the gas is very great. Darby used tubes plugged with cotton-wool, Richmond and Abel tubes plugged with asbestos, and I have tried mixing the salt with a large excess of ignited silica without success. Hence it seemed advisable to reduce the salt previous to ignition to obtain

the oxide. The reduction with hydrogen dioxide is rather tedious, and it is somewhat difficult to obtain a solution of the dioxide which leaves no residue on ignition. A solution of sulphur dioxide was therefore used as the reducing agent. 0.1539 gm. of ammonium dichromate was dissolved, reduced by sulphur dioxide, evaporated, and the residue heated for two hours at 200°, when the residue weighed 0.3228 gm., which was reduced to 0.3218 gm. by further heating during an hour and a half; this residue nearly corresponds to the formula $\text{Cr}_2\text{3SO}_4\text{7H}_2\text{O}$. After long-continued heating over a good argand, the residue consisted of a mixture of sulphate and oxide, which, when heated over a Bunsen to bright redness for two and a half hours, gave a residue weighing 0.1021 gm., which remained unchanged after heating for another hour. Hence, one part of ammonium dichromate left 0.6634 part of residue, the formula of which would be about—

instead of 0.60 required for Cr_2O_3 . A second experiment gave similar results, and even prolonged ignition over a gas blowpipe failed to produce the mass to oxide. This difficulty in drying chromic sulphate, and in decomposing it by heat, explains the high value $\text{Cr} = 53.563$ obtained by Moberg by the ignition of chromic sulphate and of ammonio-chromic alum. Reduction with (i.) hydrogen oxalate, (ii.) alcohol and hydrogen nitrate, (iii.) alcohol and hydrogen chloride is liable to occasion loss by spitting.

Mercurous Chromates.—These salts have been investigated by Vauquelin, Godon, Gmelin, Darby, and Treese, but the results obtained are not very concordant. On pouring potassium dichromate into mercurous nitrate slightly acidulated with nitric acid, a heavy orange-red precipitate falls. Gmelin states that on heating this salt Godon obtained 0.126 part, and he himself 0.1232 part of oxide. One part of $\text{Hg}_2\text{O} \cdot 4\text{Hg}_2\text{CrO}_4$ when heated would leave about 0.1232 part of oxide. According to Darby, the precipitate is of the composition $\text{Hg}_2\text{O} \cdot 3\text{Hg}_2\text{CrO}_4$, but he does not state that he himself analysed it. It is slightly soluble in water, and easily soluble in hot dilute nitric acid, from which it separates on cooling as the normal salt Hg_2CrO_4 . From one part of this salt Darby obtained by ignition (i.) 0.1463, (ii.) 0.1488, (iii.) 0.1479, part of chromic acid. Wurtz's *Dict.*, i., 896, assigns to Godon and Gmelin's salt the formula $\text{Hg}_2\text{OHg}_2\text{CrO}_4$, and Treese (*Zeit. f. Chemie* [2], vii., 30), states that the salt thus obtained is normal and not decomposed by water.

1.7334 grms. of mercurous chromate obtained from Messrs. Hopkin and Williams were heated over a Bunsen burner until a dull green residue weighing 0.1943 gm. was left. The ratio is 1 : 0.1127, and a second experiment, in which a slight loss occurred, gave 1 : 0.1118. This corresponds fairly to the salt $\text{Hg}_2\text{O} \cdot 3\text{Hg}_2\text{CrO}_4$ containing a little impurity or traces of mercurous oxide.

A hot solution of potassium dichromate was poured into a hot solution of mercurous nitrate slightly acidulated with hydrogen nitrate. The fine heavy orange precipitate was washed, dried on the water-bath, and heated at 120° C., until it ceased to lose weight. Four experiments on the ignition of this salt gave the ratios—

(i.) 1 : 0.1523	(iii.) 1 : 0.1516
(ii.) 1 : 0.1517	(iv.) 1 : 0.1510

This powder then appears to be normal mercurous chromate containing a small proportion of either mercuric chromate or mercurous dichromate. A quantity of it was boiled for some time with dilute nitric acid, and the undissolved residue was washed and dried. 1.5525 grms. left on ignition 0.2294 gm. of oxide, corresponding to the ratio 1 : 0.1477. Hence the undissolved residue seems to be normal mercurous chromate, Hg_2CrO_4 .

In conclusion, two methods for the determination of the atomic weight of chromium seem to suggest themselves:—

1st. The reduction of ammonium dichromate at a low temperature by a weak solution of hydrogen oxalate, or of

some similar reducing agent, and the determination of the chromic oxide left on ignition.

2nd. The ignition of normal mercurous chromate and determination of the chromic oxide.

In the first case the required atomic weights are well known, but the purification of the dichromate is tedious, and the reducing agent causes additional chance of error. In the second case the chromate is more easily purified, but the results will be affected by the uncertainty still attaching to the atomic weight of mercury.

58. "The Estimation of Alumina and Free Sulphuric Acid in Alum Cake and Sulphate of Alumina." By ROWLAND WILLIAMS.

The author recommends Chancel's method of estimating alumina by boiling with sodium thiosulphate (*Watts's Dictionary*, i., 1855) as more accurate and expeditious than the ammonia process. In support he quotes the following results:—

	"Ammonia" method.	"Thiosulphate" method.	Theory.
<i>Alums (pure).</i>			
Potash alum	11.01	10.76	10.81
Ammonia alum.. ..	11.50	11.24	11.31

No. 5 "	15.11	15.01	—
No. 6 "	14.81	14.68	—

The estimation of the free acid in alum cake, &c., is best effected by the following process:—300 grains of the sample are weighed into a stoppered bottle and 1200 grains measure of strong alcohol added, the contents of the bottle being frequently shaken, and the digestion allowed to proceed all night. The next morning the alcohol is filtered off and 800 grains measure of the filtrate (equal to 200 grains of the sample) titrated with decinormal caustic soda. Experiment shows that the alcohol does not extract other matters beside sulphuric acid which are liable to affect the result. To further test the accuracy of the method, ordinary sulphate of alumina was freed from sulphuric acid by washing with alcohol, and known amounts of acid were then added, and the amount estimated by the process described; the results were as follows:—

ROYAL INSTITUTION OF GREAT BRITAIN
General Monthly Meeting, Monday, July 2, 1888.

JOHN RAE, M.D., F.R.S., Vice-President, in the Chair.

THE following were elected Members of the Royal Institution:—A. Gordon Salamon, F.C.S., F.I.C., and Thomas Graham Young, F.R.S.E.

The special thanks of the Members were returned for the following donations to the Fund for the Promotion of Experimental Research:—

Ludwig Mond	£100
John Bell Sedgwick	25
Mrs. Bell Sedgwick	25

The presents received since the last meeting were laid on the table, and the thanks of the Members returned for the same.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of emperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvi., No. 26, June 25, 1888.

The Vapour Density and Molecular Weight of Aluminium Chloride.—C. Friedel and J. M. Crafts.—Aluminium chloride volatilises without fusion under the ordinary atmospheric pressure, but it melts easily under a higher pressure. The authors find its melting-point intermediate between 186° and 190°. The boiling-point at 0.33 atmosphere is 167.8°, but at 3.60, 213°. The vapour-density at different temperatures ranges from 9.69 to 8.31, the theoretical value being 9.24. The numbers found do not fluctuate greatly over a range of more than 200°, and agree fairly well with those obtained by H. Sainte-Claire Deville and Troost (9.35 in the vapour of mercury and 9.349 in the vapour of sulphur. MM. Nilson and Petterson, who began their experiments only at 440°, obtain a decidedly lower value.

At What Degree of Oxidation do Chrome and Manganese exist in their Fluorescent Compounds?—Lecoq de Boisbaudran.—This question does not receive a definite answer.

On a Property of Carbon resembling that of Platinum-sponge.—G. A. Hirn.—The author, having blown out the flame of a spirit-lamp and put on its glass cover, saw accidentally, a few moments afterwards, that a point of the wick still remained glowing. One of the carbonised points was incandescent for nine hours over the extent of a square millimetre.

Artificial Reproduction of Phenacite and Emerald.—P. Hautefeuille and A. Perrey.—The former of these minerals is obtained from a mixture of silica, glucina, neutral lithia vanadate, and lithia carbonate. Emerald was produced by using as mineralising agent acid lithia molybdate.

On the Alkaloids, the Proximate Principles of Human Urine.—Dr. Thudichum.—The substances identified and described are urochrome, omicholine, uropittine, uromelanine, urotheobromine (an isomer of theobromine differing from the latter in its properties), creatinine, reducine, parareducine, and aromine.

Bulletin de la Société Chimique de Paris.
Vol. xlix., No. 5.

Silver Nitrate in Alcoholic Solution as a Reagent for the Acetylenic Carbides.—A. Béhal.—Silver nitrate in alcoholic solution appears to be the best reagent for the acetylenic carbides, especially those of high molecular weights.

Hydration of Tolane.—A. Béhal.—The process of hydration by sulphuric acid is applicable to the aromatic series. Distillation in a current of steam separates the desoxybenzoïne formed, and possibly decomposes the corresponding sulpho-conjugated derivatives which may have been formed. This method of operating may probably be used with success in the aromatic series to obtain alcohols with ethylenic derivatives and acetones with acetylenic derivatives.

A Pretended Reaction for Phloroglucine.—MM. Cazeneuve and Hugouenq.—The authors found that Weselsky's reaction (the yellow and then orange colouration followed by a vermilion-red precipitate given by potassium nitrite) may also be produced by phenol, resorcine, orcin, naphthol α and β in aqueous solutions at 1 part in 2000.

Compounds of Aluminium Chloride with Acetonitrile, with Acetonitrile Monochloride and Trichloride.—M. Genvresse.—Not suitable for abstraction.

Action of Certain Organic Acids upon Ordinary Oxalic Ether.—M. Lorin.—Oxalic, formic, and acetic acids act upon oxalic ether under conditions quite comparable. Latent alcohol is distributed, and there is produced the ether of the acid in reaction and of formic ether, which is in a twofold proportion when the reacting acid is the oxalic. The gaseous phenomena are of the same order.

Contributions to the Study of the Chlorides of the Bibasic Acids.—V. Auger.—The author examines the action of succinyl chloride upon benzene in presence of aluminium chloride; that of the same chloride upon ammonia, both aqueous and dry, and the action of aqueous ammonia upon phthalic anhydride and upon phthalyl chloride.

The Acetals of Normal Propyl-glycol.—H. Locher.—In this paper the author examines merely the cases of acetic and isovaleric aldehyds.

No. 6.

Examination of an English Coal.—MM. Scheurer-Kestner and Meunier Dollfus.—Already noticed.

Infusible Blue-black Enamel and its Applications on the Covering of Hard Porcelain.—Charles Lauth.—The author points out certain defects in the pure cobalt blues, and recommends, in preference, a mixture of 100 parts cobalt oxide, 88 parts manganese peroxide, and ferric oxide 44 parts. This mixture gives blues of a slightly grey tone, very soft, harmonising well with the whites and retaining its beauty by artificial light.

On the Covering Shell of Hard Porcelain.—Ch. Lauth and G. Dutailly.—The author discards the formula of Brongniart, on account of its tendency to chip off, and uses a mixture of sand, 37.69, kaolin, 35.38, manganese dioxide, 21.54, and colcothar, 5.39. After being twice furnace this mixture gives;—Silica, 57.36; alumina, 14.20; manganese peroxide, 22.77; ferric oxide, 5.69.

Researches on Soft Porcelain.—Ch. Lauth and G. Dutailly.—This bulky memoir does not admit of abridgment.

Synthetic Formation of Toluyl-propionic Acid.—E. Burcker.—The author causes succinic anhydride to act upon toluene in presence of anhydrous aluminium chloride, and thus obtains tolyl-propionic acid. The reaction begins and may even be continued and completed at the common temperature.

Action of Chlorine upon Metallic Gold.—M. Lindet.—The author, on treating spongy metallic gold with chlorine, obtains a mixture of gold tetrachloride, gold monochloride, and metallic gold. As the temperature rises the proportion of the two chlorides increases at the expense of the metallic gold.

The Active Crystalline Matter of the Poisoned Arrows of the Somalis, extracted from Ouabão Wood.—A. Arnaud.—This principle, which is not an alkaloid, is exceedingly poisonous, a few in.grms. proving fatal to large animals in a few minutes. It acts upon the heart.

Researches on the Colloidal State.—C. Winssinger.—The most remarkable conclusion reached is that the aptitude of the sulphides to assume and retain the colloidal state seems to be a periodic function of the atomic weights of the corresponding elements.

No. 7.

Action of Mono-chloro-acetonitrile upon Benzene in Presence of Aluminium Chloride.—P. Genvresse.—The principal products are benzoic acid and orthotoluic acid, the latter in small quantities.

On Blues under Cover.—Ch. Lauth and G. Dutailly.

Transformation of Cēnanthylidene and Caprylidene, True Acetylenic Carbides, into Substituted Acetylenic Carbides under the Influence of Alcoholic Potassa.—A. Béhal.

Researches on Copper Reds.—Ch. Lauth and G. Dutailly.—These two long and exhaustive memoirs do not admit of abridgment. They are of the greatest value to artists on porcelain.

NOTES AND QUERIES.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1495.

COMBUSTION OF OXYGEN IN AMMONIA AND HYDROGEN IN NITRIC ACID.

By Dr. HODGKINSON and F. K. LOWNDES.

THE experiment of burning oxygen in ammonia may be slightly modified by using a long platinum jet about 1 m.m. bore and 8 or 9 c.m. long. A good form of the experiment is to have the strong ammonia, 0.880, in a half litre flask with wide neck. Introduce the platinum tube, with escaping oxygen, to within a c.m. of the surface of the liquid, and set fire to the escaping gas mixture. The oxygen burns at the jet and raises the point to a white heat, whereupon it is lowered into the liquid ammonia. Here the oxygen continues to burn, and the platinum tube is generally melted. With a certain amount of oxygen pressure, easy to ascertain by a trial or two, white fumes of ammonium nitrate and nitrite escape from the flask or coat the upper part of the neck.

The converse experiment to this with hydrogen and nitric acid is still more striking. On introducing a small hydrogen flame by the platinum tube into concentrated nitric acid in the same sized flask as the ammonia experiment, several appearances may be obtained depending on the amount of hydrogen. With the platinum tube at a distance of 2 c.m. from the surface of the acid, and the pressure so arranged that the flame just touches the acid, the jet becomes heated to whiteness, and a fine coloured conical flame extends from the neck of the flask to the liquid surface, and white fumes of ammonium nitrate or nitrite escape. If the white-hot point of the tube be immersed under the acid, red fumes escape as well. The hydrogen continues to burn under the acid until it becomes considerably diluted. It is comparatively easy to regulate both experiments so as to produce ammonium salts.

DETECTION AND ESTIMATION OF BISMUTH AND LITHIUM IN METALLIC IRON AND SLAGS.

By H. N. WARREN, Research Analyst.

THE slags operated upon in which the lithium and bismuth were detected were of ordinary blast-furnace production, and obtained from the smelting of ore from the Cleveland district, and consisting of an ordinary blast slag composition. Six slags, out of nine samples examined, gave a decided brownish precipitate after transmitting a current of SH_2 through a HCl solution containing 1 grm. of dissolved slag, and when 5 grms. were employed a decided black precipitate, which, when purified and estimated by the usual method, amounted in the various cases from 0.1 to 0.5 per cent of Bi_2O_3 . The lithium estimated as carbonate, after the separation of the other ingredients, averaged from 0.05 to 0.1 per cent. The samples of iron examined, from which the slag had been produced, gave, as a mean percentage, from 0.01 to 0.04 of metallic bismuth, practically speaking the whole of the bismuth thus present passing into the slag. Out of six samples of the cast-iron examined, four samples, after separation of the iron and other ingredients present had been effected, gave, on attaching a small quantity of the residue to a platinum wire, and suspending the same in the flame of a Bunsen

burner, a spectrum decidedly characteristic of lithium, when viewed by the aid of the spectroscope.

ON THE DETERMINATION OF THE AMOUNT OF MORPHIA PRESENT IN OPIUM.

By ROWLAND WILLIAMS.

IN the CHEMICAL NEWS (vol. lvii., pp. 244—245) there appeared a paper by Messrs. Teschemacher and Smith. In justice to myself I must ask permission to correct a few of the errors contained therein.

Messrs. Teschemacher and Smith accuse me of adopting the title of their original paper without acknowledging its source. Now, in the *very first sentence* of my paper (CHEMICAL NEWS, vol. lvii., p. 134) I use the following words:—"I have read with much interest the paper bearing the above title by E. F. Teschemacher and J. Denham Smith, which recently appeared in the CHEMICAL NEWS (vol. lvii., pp. 93 and 103)."

Notwithstanding the disclaimer of Messrs. Teschemacher and Smith I still maintain that they were "in the same predicament" as myself with reference to the quantity of opium solution specified in the B. P. process. They seem to think they were bound to follow the process exactly, but that the same restriction did not apply to myself. If I worked by the B. P. process at all, it was quite as necessary for me to obey the instructions precisely as it was for Messrs. Teschemacher and Smith.

Messrs. Teschemacher and Smith next make the charge that I have been guilty of plagiarism from Mr. Stillwell. By reference to my letter to the CHEMICAL NEWS (vol. lv., p. 69), which Messrs. Teschemacher and Smith quote in connection with the question of titrating morphia with acid, they must have been aware that I had already given every credit to Mr. Stillwell.

Notwithstanding Messrs. Teschemacher and Smith's remarks about "my series of experiments," I again assert that for some time previous to the appearance of Mr. Stillwell's paper "On the Analysis of Opium" (CHEMICAL NEWS, vol. lv., pp. 41 and 54) I had been working on very similar principles to those laid down by him. In fact, when Mr. Stillwell's paper appeared I was engaged on an article for the CHEMICAL NEWS on the same subject, and was naturally rather disappointed to find myself forestalled. Consequently, I wrote the letter to the CHEMICAL NEWS, to which reference has already been made, and therein I explained the three chief points of difference between Mr. Stillwell's and my own plan of working. The most important of these is, I think, undoubtedly the third, viz., titration of the morphia with standard acid. The idea of claiming the titration with acid as original never entered my head, as the process has, I believe, been well known for some years in connection with other alkaloids besides morphia.

All that I urged was that titration with acid was decidedly preferable to treating the morphia precipitate with hot alcohol, as recommended by Mr. Stillwell, and I may say that Messrs. Teschemacher and Smith agree with me on this point.

Messrs. Teschemacher and Smith speak of my "curt and meaningless directions concerning the process which I at present employ for estimating morphia in opium." Surely it was unnecessary to repeat the exact details of manipulation, which I had already given on the previous page, the chief difference between the two processes being in the quantities of the respective reagents.

Messrs. T. and S. state that the change in my present method consists simply in using double the quantities which I formerly employed. As a matter of fact I use only *half* the amount of alcohol and *three-fourths* of the

quantity of ammonia of an entirely different sp. gr., the ether alone remaining in the same proportion as before.

Messrs. Teschemacher and Smith seem to doubt my statement concerning the results which I obtain by titrating the purified morphia precipitate. I still find my final figures to be about 0.25 per cent lower than those obtained by simply weighing the morphia. Our difference of opinion on this point may perhaps be partly due to the fact that I use *cold* water, whilst Messrs. Teschemacher and Smith use *warm*, for extracting the opium. Anyone who has worked by the two processes will certainly admit that my plan of working yields much cleaner and presumably, therefore, purer morphia, than Messrs. Teschemacher and Smith's method.

There is, however, not much difference between us in this respect. In their previous paper (CHEMICAL NEWS, vol. lvii., p. 103) they refer to a table on p. 94, and state that "the morphia crystals, freed from the rest of the opium alkaloids and from narcotin, lose very nearly 1 per cent in weight by titration." Now, on reference to this table I find that as the analyses were all made on *two hundred grains* of opium the actual average loss on titration was only 0.40 per cent, the highest being 0.52 per cent and the lowest 0.30 per cent.

I am surprised at Messrs. Teschemacher and Smith asserting that my statement is "wholly opposed to their own experience," when it is evident that their own figures, if correctly interpreted, prove beyond doubt the essential accuracy of my results.

Laboratory and Assay Office,

July 9, 1888.

PHENOL AND SOME ALLIED BODIES AS TESTS WITH CONCENTRATED SULPHURIC ACID FOR NITRITES, NITRATES, AND CHLORATES IN AQUEOUS SOLUTION.

By DAVID LINDO.

(Concluded from p. 17).

Nitrite and Chlorate.

In all cases equal volumes of the nitrite and chlorate solutions mixed. Sulphuric run in immediately after adding the other reagents.

20,000 N_2O_3 and 40,000 Cl_2O_5 . Gave good red band with phenol. With 1 drop SO_2 and 1 drop orcinol blue band only. Nitrite destroyed, blue band due to chlorate faint.

10,000 N_2O_3 and 20,000 Cl_2O_5 . Tested as above. Strong red band with phenol, blue band with orcinol distinct.

2000 N_2O_3 and 10,000 Cl_2O_5 . Tested for chlorate only. Very distinct blue band.

4000 N_2O_3 and 20,000 Cl_2O_5 . Tested as above. Blue band sufficiently distinct.

4000 Cl_2O_5 and 10,000 N_2O_3 . Tested for nitrite only. Red, weak, and rusty.

10,000 Cl_2O_5 and 20,000 N_2O_3 . Tested for nitrite only. Red, weak.

Results show chlorate can be detected when mixed with a considerable excess of nitrite after destroying the latter with SO_2 , but the nitrites cannot be detected by this method if chlorate is greatly in excess.

Nitrate and Chlorate.

N_2O_5 in Equal and Excessive Proportion.—The following mixtures were tested for chlorate only by adding 1 drop orcinol and 2 c.c. sulphuric acid as usual.

Equal volumes 40,000 N_2O_5 and 40,000 Cl_2O_5 . Blue band distinct.

Equal volumes 10,000 N_2O_5 and 10,000 Cl_2O_5 . Blue to rainbow band.

Equal volumes 5000 N_2O_5 and 10,000 Cl_2O_5 . Blue soon changed to green.

Equal volumes 4000 N_2O_5 and 20,000 Cl_2O_5 . Not satisfactory.

Therefore the chlorate will not be detected if nitrate is present in considerable excess.

Chlorate in Enormous Excess.—Equal volumes of 300 Cl_2O_5 and N_2O_5 60,000. The Cl_2O_5 is present in this mixture in the proportion of 200 to 1 N_2O_5 , and the dilution of N_2O_5 is 120,000. It was tested for nitrate only. 4 tests were made and 4 comparative with 120,000 N_2O_5 . Added to each 2 drops SO_2 and HCl. Set rest fifteen minutes, then added 2 drops orcinol and sulphuric as usual—pure nitrate bands in all; comparative test not to be distinguished from the others. Result shows, if nitrate is mixed with enormous excess of chlorate, the latter can be easily and completely destroyed by SO_2 , while the nitrate remains unaffected and can be detected afterwards. This is the best method; yet I should observe, if the quantity of chlorate is not excessive, the nitrate can be detected with phenol and HCl without destroying the chlorate. Equal volume 10,000 N_2O_5 and 10,000 Cl_2O_5 gave excellent results. 1000 Cl_2O_5 and 5000 N_2O_5 fairly good by this method.

Nitrite, Nitrate, and Chlorate.

Mixed equal volumes of 10,000 N_2O_3 , 10,000 N_2O_5 , and 10,000 Cl_2O_5 . Tested with phenol, red band; with 2 drops SO_2 and phenol, no band; nitrite destroyed, nitrate latent. Chlorate at this dilution gives no band with phenol in presence of SO_2 . If much more chlorate were present a band (hardly characteristic) would be seen at this stage. The band has already been described (see Phenol and Chlorates). Tested with 1 drop SO_2 and 1 drop orcinol blue band only—chlorate. Tested again, adding 2 drops SO_2 , 1 drop HCl, and allowing the test to stand fifteen minutes, then added copper and orcinol, beautiful orange bands at once; nitrite and chlorate destroyed by SO_2 , bands due to nitrate.

Previous experiments have shown—

1. That the proportion of nitrite might be considerably increased without preventing the detection of chlorate, and very largely increased without interfering with detection of nitrate.
2. That the proportion of nitrate might be very greatly increased without interfering with the detection of nitrite, but could not be largely increased without preventing the detection of chlorate.
3. That the presence of much more chlorate would prevent detection of nitrite, but an enormous excess would not prevent detection of nitrate.

Colour Reactions Produced by Oxidising Agents free from Nitrogen, with Phenol and Orcinol.

The reactions with chlorates have been already described, those with ferricyanides, permanganates, chromic acid, and hydroxyl will now be given. If the solutions are strong they all produce intense brown or ruddy brown bands; it is only with weak solutions that bands possessed of any distinctive character are ever obtained. I have described these reactions merely to show that the bands are entirely different to those produced with nitrogen acids, and therefore that the presence of these oxidising agents should never lead to error in testing for nitrites and nitrates. 0.5 c.c. solution of the oxidising agent for each test, 1 drop phenol to this or 1 drop orcinol.

Potassic Ferricyanide.

A strong solution turns brown with sulphuric acid alone; a weaker not so affected by the acid, gave brown band with phenol and faint yellow turning brown with orcinol.

Potassic Permanganate.

N/10 diluted with 4 volumes of water.

Phenol.—Broad, turbid, light ruddy brown band. With HCl, pale yellow broad upper band; narrow lower ruddy band, changing on standing to light vermillion.

Orcinol.—Compound band, ruddy top, dull green below. With HCl, compound band, dull orange top, emerald green below.

If 2 drops SO₂ added before anything else, no band on adding the other reagents.

Potassic Dichromate.

Half grm. in 1 litre of water.

Phenol.—With or without HCl, brown band soon gets lighter.

Orcinol.—With or without HCl, rainbow band, colours not brilliant.

If 2 drops SO₂ added before anything else, no band on adding the other reagents. This distinguishes chromates from chlorates; if both are present blue band appears, although SO₂ was used. This due to chlorate *only*, the chromic acid having been reduced.

Hydroxyl.

About 3 volumes strength diluted with 20 volumes water.

Phenol.—Compound band, ruddy top, and dull green below. With HCl, very faint purple, changing to pink.

Orcinol.—Sharp ruddy band on standing changes to compound band, dull orange top, olive green below. With HCl, purple top band, lower band as above but weaker; if SO₂ used no bands.

Remarks and Conclusion.

It has been clearly shown that orcinol is very superior to phenol as a test for either nitrites or nitrates; it is far more delicate even without copper, the bands are very permanent, while those with phenol are not, and it will detect nitrates in the presence of bodies that would interfere with the phenol reaction, *e.g.*, a large quantity of HCl or chlorides, iron in the state of ferrous salt. It is true phenol gives a rather finer band in presence of much ferric iron, but if the experiment is repeated with addition of SO₂ the orcinol band becomes normal, whereas the phenol band may disappear completely. This should be noted, as it might lead to the erroneous conclusion that the band was originally due to nitrite.

As regards carbohc acid, the following passage occurs in "Fresenius's Qualitative Analysis," Ninth English Edition, p. 208. "Of the reactions which have been given to effect the detection of nitric acid, those with sulphate of protoxide of iron and sulphuric acid, with copper filings and sulphuric acid, with carbohc acid, and also those based upon reduction to nitrites, give the most positive results."

Now this statement as regards the reliability of carbohc acid is contradicted in the Tenth Edition, p. 234, in the following sentence:—"Chloric acid behaves like nitric acid with brucine, diphenylamine, paratoluidine, and phenol, or at all events the reactions are so similar that the two acids cannot be distinguished with certainty by these reagents."

This may be true if the phenol test is applied to a dry residue or strong solution, but, it is hardly necessary to add, is certainly *not* true if the experiment is made with a sufficiently dilute solution, as pointed out in this paper.

It is evident that phenol and orcinol (particularly the latter) are of great value as reagents for the detection of nitric acid; they will also be found, under certain conditions, very convenient for nitrites, especially in the absence of Griess's or Meldola's reagents.

It is not, however, pretended that they are at all equal for this purpose to those exceedingly delicate and characteristic tests for nitrous acid.

NOTES.

Orcinol.

It would appear that dealers in reagents only recognise this phenol by the old name orcin, for on sending an order for orcinol to one of the largest drug houses in London I was informed that the article was unknown, but orcin could be supplied. I had to wait several months in consequence before obtaining it, and was obliged to work in the meantime with a very old sample, which had been in my possession fifteen years. It was highly coloured, but rather more sensitive as a reagent for nitrites and nitrates than the fresh sample (almost colourless) with which the work here recorded has been done. There was this marked difference: the old sample gave a pronounced orange band with nitrites or nitrates and HCl, even at the highest dilutions, whereas the new has always given at these dilutions pink or orange-pink bands. This new sample is in good crystals and seems to be pure, but it is possible other samples in the market may react somewhat differently to the one I have used. The absolute purity of any of them is perhaps open to doubt.

Copper Orcinol Reagent.

a. Take 25 c.c. 2 per cent solution pure copper sulphate (crystals), add 1 c.c. pure sulphuric acid, stir well, and after a few minutes add 25 c.c. pure 15 per cent HCl. Dissolve 2.5 grms. orcinol in this mixture and filter.

b. Dissolve 2.5 grms. orcinol in 50 c.c. distilled water, add 8 grms. potassic chloride, 0.5 grm. copper sulphate (at once), 1 c.c. sulphuric acid (all pure); when dissolved, filter.

a is a little more sensitive than *b*, but the latter may possibly keep better. How long either can be kept fit for use has not yet been ascertained. They should be preserved in glass stoppered bottles away from the light.

The reagent is exceedingly convenient for the detection of either nitrites or nitrates, but is *not* suitable for chlorates. Add 2 drops to 0.5 c.c. of the solution to be tested and run in 2 c.c. sulphuric acid. If reaction (as described) occurs in the presence of SO₂, this, of course, indicates nitrates.

α-Naphthol.

It has been shown this phenol is not available as a test with sulphuric acid for nitrites or nitrates; it can, however, be used for the detection of the former by adding 2 or three drops of the alcoholic solution to, say, 10 c.c. of the aqueous solution of nitrite in a test-tube, then one or two drops of 1 to 1 sulphuric acid. If the quantity of N₂O₃ is one in a million a pale greenish yellow colour is seen after a few minutes, best observed at this dilution by looking down the tube on a white surface; with much stronger solutions a precipitate occurs, and the colour of the fluid may approach orange. The reaction seems quite characteristic of nitrous acid.

Tube Rack.

The racks in ordinary use were found inconvenient for this work; the wooden draining pegs are apt to soil the tubes after they have been carefully cleaned and rinsed with distilled water. Draining pegs are dispensed with in the rack I have contrived; the inverted tubes rest on a glass rod, and a centre slide has been provided, which is indispensable. Messrs. Townson and Mercer, London, have been furnished with a pattern of my rack, and will no doubt supply similar ones if required.

Drop Tubes.

Drop tubes very suitable for delivering the reagents are made of short pieces of strong ¼-inch tube drawn to a thick blunt point with small orifice; a short piece of black rubber tubing is placed over the free end and closed at the other extremity with a short piece of glass rod.

Falmouth, Jamaica, B.W.I.,
May 12, 1888.

THE RELATIVE VALUES OF THE WEIGHTS
OF HYDROGEN AND OXYGEN.*By JOSIAH PARSONS COOKE and
THEODORE WILLIAM RICHARDS.

(Concluded from p. 20).

Apparatus for Preparing Hydrogen.

In the preliminary determinations, the hydrogen was drawn from a large copper generator charged with zinc and dilute sulphuric acid. The zinc and sulphuric acid was wholly free from arsenic, and of the best quality, but not absolutely pure; and the writer depended upon an elaborate system of washers and driers for purifying and drying the gas. He found the greatest difficulty in removing the last-traces of sulphurous oxide, which hydrogen prepared in this way always carries. The presence of this trace cannot be detected by litmus-paper, but is immediately indicated by the production of hydric sulphide when the gas is passed over heated platinum sponge; and by interposing a tube containing platinum sponge maintained at a low red heat, followed by a set of potash bulbs, this impurity can be entirely removed. It can also be removed by washing with a strong solution of potassic hydrate alone, if the gas remains long enough in contact with the solution. It was found, however, that a series of potash bulbs was insufficient for this purpose; but two of the long washers represented in the background of Fig. 5 and Figs. 7 and 8 (*ante*), where the gas in small bubbles travels up a tube $5\frac{1}{2}$ feet long, are sufficient to remove the sulphurous oxide from even a quite rapid current of hydrogen gas. A series of preliminary determinations was made with hydrogen gas thus prepared and purified, and it was obvious from an inspection of the results, as well as from the difficulties which were experienced in keeping all the joints of this complicated apparatus tight, that the irregularities arose from the diffusion of the air into the hydrogen at some one or other of these joints. It was therefore next sought to simplify the apparatus, and to depend upon the purity of the materials rather than on the completeness of purifying methods for obtaining pure hydrogen. Meanwhile, for reasons stated below, the writer had reduced very materially the scale of his operations, and this rendered unnecessary the large generator we had first employed.

The second apparatus that was constructed is represented in Fig. 5 (*ante*). Of this, the generator, in which hydrogen is made from pure zinc and hydrochloric acid, is the same as that described by Julius Thomsen.† The Wolff bottle is filled with pure granulated zinc, and the upper bottle contains pure hydrochloric acid diluted about one half. By means of a glass stopcock the acid is allowed to flow into the zinc drop by drop, and in this way the current of hydrogen can be quite closely regulated. Tubes protected by stopcocks are provided for adding fresh charges of acid, and for drawing off the solution of zinc chloride; also a tube connecting the upper part of the two bottles enables the operator to effect these transfers without introducing any air. The gas from this generator passed first through a long potash tube inclined at about 10° to the horizon, then through a tube about three feet long filled with calcic chloride, then through a glass tower filled with glass beads drenched with sulphuric acid, and lastly through a second tower filled with phosphoric pentoxide. As many of the joints as possible were made by fusing together the glass, and all the others were protected by a cement consisting of equal parts of pitch and gutta-percha. It will be noticed that an overflow is provided at the point where the potash tube connects with the calcic chloride tube, the open mouth of the overflow tube dipping about six or eight inches deep under concentrated sulphuric acid.

This overflow indicated the least change of tension of the hydrogen in the apparatus, and would have shown the least leak if it had existed; but the apparatus as thus constructed remained absolutely tight so long as it was in use.

With the hydrogen drawn from this apparatus the first determinations were not wholly satisfactory, and the cause of error was traced to the air dissolved in the dilute hydrochloric acid with which the generator was charged. In all the succeeding determinations the greatest pains were taken to remove the last traces of air by boiling the dilute acid, and allowing it to cool in a stream of hydrogen; and as additional precaution, while the solution was still warm, the gas was exhausted from the containing vessel and pure hydrogen run in, several times in succession, the pure acid being finally conveyed into the generator entirely out of contact with the air. The need of all these precautions will be seen when it is considered how small an admixture of air or of nitrogen will materially influence the weight of the hydrogen. If only one ten-thousandth of the volume of the hydrogen were replaced by air during the process of filling the globe, this would cause an apparent increase of weight in the hydrogen of five-tenths of a milligram., and that, other things being equal, would reduce the atomic weight of oxygen two-hundredths of a unit.

The precautions used in filling the globe have already been described in detail, and with hydrogen from the apparatus, constructed and charged as just described, were made the five consecutive determinations whose results are given as of the first series in the "Table of Final Results" (p. 32). These and all the determinations given in the Table were made by the writer's pupil and assistant, Mr. Theodore William Richards, to whose experimental skill the success of the investigation is largely due, and without whose assistance the work could not have been completed in the present condition of the writer's sight. The mean of these first five results, as will be noticed, is but little less than that obtained by Dumas, and the probable error, ± 0.0048 , is considerably less than that of Dumas. In order to understand how this result appeared to the writer, it must be remembered that he started with a certain prepossession in favour of the hypothesis of Prout, based on his previous work on antimony; and, furthermore, that the effect of the causes of error which had been encountered and overcome all tended to lower the atomic weight; and the result obtained was a maximum which had been reached after every known precaution had been taken. But although this maximum was essentially the same as that obtained by Dumas by an obviously less direct and less accurate method, yet it was still possible that there might be some constant error, and that some cause might yet be found which would raise the maximum by the forty-six thousandths required to give the whole number 16. It was true that the probable error was only about one-tenth of this difference; still, as the materials had been purified, the maximum had constantly risen, and the theoretical limit was in sight. In reviewing the work it was obvious that the degree of accuracy of the methods used for determining the weights both of the hydrogen and of the water was so great that no possible error in these values could account for the difference in question. This would imply an error of 1.2 milligrams. in the weight of the hydrogen, and of 10.8 milligrams. in the weight of the water, and the possible error of a single determination—leaving out of account the reduced probable error of the average value—was far within these limits. If there was a constant error, it must result from the want of purity of the hydrogen gas, and we therefore determined to try another method for preparing the hydrogen.

The apparatus next used is represented in Fig. 7 (*ante*), and differs from the last only in the generator. Here the generator is a three-necked bottle having a capacity of about two litres, filled to about one-eighth of its capacity with a semi-fluid amalgam of mercury and pure zinc. On this rests dilute hydrochloric acid, containing about 20

* Contributions from the Chemical Laboratory of Harvard College. From the *Proceedings of the American Academy of Arts and Sciences*, vol. xxxiii.

† *Thermochem. Untersuch.*, vol. i., p. 28.

per cent of HCl, nearly filling the bottle. Into this acid dips a platinum electrode, while a straight glass tube, passing through the middle neck and dipping under the amalgam, gives the means of establishing an electrical connection between the large platinum plate which forms the negative electrode and the amalgam. In addition, a syphon tube for drawing off the acid when saturated with zinc, a funnel tube for introducing a fresh charge, and an exit tube, all well cemented to the several necks of the bottle, complete the generator. When the electrical connection is broken all chemical action ceases, but on connecting by a wire the platinum electrode with the amalgam, a very steady but slow evolution of hydrogen gas takes place, which can be regulated with the greatest nicety by varying the resistance of the connecting wire. On interposing two cells of a Bunsen battery the evolution of gas becomes very rapid. Besides its special use in this connection, the apparatus will be found of great value, as giving an absolutely constant source of pure hydrogen, whenever required. In charging the generator with acid, the same care was taken to exclude every trace of air as with the previous apparatus, and with hydrogen thus prepared a second series of five consecutive determinations were made, whose results are given in the Table on p. 32 below those of the first series; it will be noticed that, while the average value obtained is essentially identical with the previous result, the agreement of the several determinations is more close, and, in consequence, the probable error is reduced more than one-half. A closer agreement under the circumstances could not possibly be expected.

Such a striking confirmation of the previous result seemed very conclusive, and the very small probable error indicated a command of the method which was very satisfactory. Still it could not be proved that there might not be a constant impurity in the hydrogen used. As the hydrogen had passed every possible chemical test unimpeached, the only possible impurity that could be suspected was nitrogen, and Mr. Richards therefore made a careful spectroscopic examination, searching for the more conspicuous nitrogen lines in the spectrum obtained by passing an induction current through a rarefied atmosphere of the gas from the generator just described; but not the faintest trace of any of these lines could be seen.

Still, as in the electrolytic method of preparing the hydrogen the same materials, hydrochloric acid and zinc, were used as in the first series of experiments, it was determined to procure hydrogen by a wholly different chemical process, using the well-known reaction of metallic aluminum upon a solution of potassic hydrate.

The purest aluminum sheet that could be obtained in the American market was procured for the purpose, and the apparatus represented in Fig. 8 (*ante*) was used for generating the gas. The generator here was a simple flask holding a strong solution of chemically pure potassic hydrate, and the aluminum was introduced in small pieces through a large open tube—dipping under the surface of the solution—the liquid being maintained at a level near the open mouth of the tube by the tension in the interior of the apparatus. The small strips of aluminum were carefully cleaned, and caused slowly to slide down the tube; the evolution of hydrogen from the surface began as soon as the strips of metal touched the liquid, and became very active in the tube before they dropped into the flask. And this action insured the removal of any traces of air which might adhere to the surface. In this apparatus the long caustic potash washer was not used, as being no longer necessary, and the gas was passed through caustic potash bulbs to remove the spray, and then through a calcic chloride tube, and over sulphuric acid and phosphoric pentoxide as before.

With hydrogen thus prepared, the six determinations of the third series in the Table were made; and it will be seen that the average of the results is a value which is essentially identical with the average values from the other two series. The probable error in this last series is larger

than in the second, although still very small; but the difference is due, as the note-books plainly show, to the different conditions under which the two series were made. As before stated, the compensation of the balance was perfect, and the apparent weight of the globe did not alter by a tenth of a milligram, even with wide variations of temperature and pressure, so soon as those changes became constant. But when the changes of temperature in the balance-room were rapid, currents of air were established in the case, however great care was taken in protecting it, which rendered the apparent weight irregular to the extent of one- or two-tenths of a milligram; and the third series was made under less favourable conditions in this respect than the second. This point is illustrated by the following notes of two determinations which are given in full, in order that all the circumstances connected with the determinations may be seen.

On examining the Table, it will be noticed that the mean of the determination by the electrolytic method is the mean of all the determinations combined, and that the probable error of the total average is only about one-fourth as great as the error of the nineteen determinations of Dumas, which are incomparably the best that have hitherto been made.

It does not now seem possible to escape from the conclusion, that the proportions in which the purest hydrogen that can be made combines with oxygen to form water are those of 2 to 15.953, with a possible error far within the $\frac{1}{100}$ of a single unit.

The question, of course, still remains, is the hydrogen thus prepared the typical hydrogen element? But this is

ATOMIC WEIGHT OF OXYGEN.

the same question which must arise in regard to any one of the elementary substances; and all that we can say is that the evidence in regard to the purity of the hydrogen we have used is as good as any that can be adduced in regard to any one of the elementary substances whose atomic weight has been most accurately determined. The question as regards Prout's hypothesis narrows itself now to this one point; and here we must be content to leave it until further investigation has given us more knowledge in regard to the nature of elementary substances.

The writer at first planned to carry out the investigation on a much larger scale, and for the purpose had blown a globe similar to that represented by Fig. 1, but of five times the capacity, and counterpoised it by the same general method. This globe held twenty-five litres (somewhat over two grms. of hydrogen gas), or five times as much as the globe actually used; but the difficulties of carrying out the determinations on this scale led him to reduce the scale of the determinations to that actually adopted; and in the view of the results finally reached, it is evident that no appreciable advantage would have been gained from the enormous expenditure of time and labour which the process on a large scale involves. Assuming that the difficulties of preparing pure hydrogen gas on that scale could have been overcome, it would have required from five to seven hours to fill the globe, and four or five days continuously to complete the combustion.

Moreover, after many trials, the writer could not procure a globe that would stand the requisite pressure weighing less than two and one-half kilograms., and with this weight and volume it was not possible, with the best balance he could command, to distinguish half a milligram. with as much accuracy as he could one-tenth of a milligram. with the smaller apparatus, while a vastly longer time was required to reach equilibrium. A great deal of time was spent in endeavouring to perfect this larger apparatus, and a very thorough knowledge was acquired of its relative efficiency. The greatest gain that could have been expected in carrying out the work on this scale

would have been the reduction of the probable error to about one half of the present amount, but it is obvious that this gain could be of no importance in the present condition of the science. The accuracy we have reached is far beyond the demands of any analytical work; and, as we have shown, the theoretical question in regard to Prout's law has been settled so far as analytical work can solve the problem. It now turns solely on the typical character of the material we call hydrogen, when prepared in the purest condition known to modern science.

In considering the bearing of the result now published on Prout's hypothesis, it must be borne in mind that it confirms in a most striking manner the result of Dumas, based on the weight of oxygen which water contains, and in connection with his results furnishes a complete analysis of water with a degree of accuracy as great as can be expected, or as has ever been obtained, in any analytical work.

Complete Analysis of Water.

Percentage of oxygen after Dumas ..	88.864 ± 0.0044
Percentage of hydrogen according to the present work	11.140 ± 0.0011
	100.004 ± 0.0045

It must be remembered that in Dumas's investigation the oxygen alone was weighed, while in the present investigation the hydrogen alone was weighed, and the fact that these two wholly independent analytical results made under such widely different circumstances, exactly supplement each other within the limits of probable error, is an evidence of accuracy and a proof of finality which is irresistible.

It would have been highly desirable, if it had been possible, to determine both the oxygen and the hydrogen in one and the same analytical process, as the writer succeeded in doing in the case of silver, bromine, and antimony, and he made many experiments on the reduction of oxide of silver by hydrogen with this view. He succeeded in preparing pure oxide of silver of definite composition, but the investigation was interrupted by the failure of his sight before he was able to overcome the grave experimental difficulties which the process presented. In view, however, of the present results, it is doubtful whether any advantage would have been gained by that mode of experimenting, for no more certain confirmation could have been reached than that furnished by a comparison of Dumas's results with those of this paper.

Since this investigation was essentially finished, and the results communicated to the American Academy at their meeting of June 15, 1887, we have received from the author a "Sonderabdruck" from the *Berichte der Deutschen Chemischen Gesellschaft*, dated the 26th of July following, and entitled: "E. H. Keiser: Ueber die Verbrennung Abgewogener Mengen von Wasserstoff und über das Atomgewicht des Sauerstoffs." In this paper Mr. Keiser distinctly recognises the importance of directly weighing the hydrogen in the determination of the atomic weight of oxygen, and quotes the remarks of Dumas given above. He has also devised a very ingenious method of weighing hydrogen when occluded by palladium; but the preliminary results he publishes are far from having the degree of accuracy required, and lead us to infer that, like our own preliminary results, they must be vitiated by varying impurities in the hydrogen gas used. The three determinations whose results he publishes gave for the atomic weight of oxygen, respectively, 15.873, 15.897, and 15.826.

We are sorry if Mr. Keiser has entered on somewhat the same field which we have so long occupied, without knowledge of our work. But, as above stated, our investigation was begun more than five years ago; and the methods employed have been freely explained to the many chemists, both American and European, who have

visited Cambridge during the interval. We earnestly hope that Mr. Keiser will carry out his investigation; for so important a constant as the atomic weight of oxygen cannot be too often verified.

POISONS AND POISONING.*

By C. MEYMOTT TIDY, M.B., M.S., &c.,
Professor of Chemistry and of Forensic Medicine at the London Hospital, &c.

TOXICOLOGY is the science of "poisons and poisoning." How comes "toxicology" to mean "the science of poisons"? The Greek word *τόξον* (derived perhaps from *τοξάειν*) signified primarily that specially oriental weapon which we call "a bow." In the very earliest authors, however, it included within its meaning "the arrow shot from the bow."

In the first century A.D., in the reign of Nero (a poisoner and a cremationist), Dioscorides, a Greek writer on *Materia Medica*, uses the expression *τὸ τοξικόν* to signify "the poison for smearing arrows with." Thus by giving an enlarged sense to the word—for words ever strive to keep pace, if possible, with the scientific progress—we get our modern and significant expression "Toxicology," the science of poisons and poisoning.

And there, in that little piece of philology (*τόξον* and *τοξικόν*—a bow and a poison), you have not only the derivation of the word, but the early history of my subject.

A certain grim historical interest gathers around the story of poisons and poisoning. It is a history worth studying, for poisons have played their part in history.

The "subtil serpent" taught men the power of a poisoned fang. History presents poisoning in its first aspect in a far less repulsive form than it has assumed in latter days—for a world may grow wiser and wicked withal. Poison was in the first instance a simple instrument of "open warfare." For this purpose our savage ancestors tipped their arrows with poison in order that they might inflict certain death on a hostile foe. It can scarcely be questioned that the poison of the snake was the first material employed for this object. The use of vegetable extracts (such as *curarine*, the active principle of which is strychnine, and is employed at the present time by certain uncivilised communities) belongs to a later period.

And so the first use of poison was for an "open fight." It was reserved for later times to mix the cup of kinship with a treacherous, diabolical venom!

"An open fight!" Is the suggestion (think you) too wild, supposing "war chemists" with their powders, their gun-cotton, and their explosives, never to have been invented, that nations would have turned for their "*instrumenta belli*" to toxicologists and their poisons. I claim, however (notwithstanding that in this we missed our chance), no more for my subject than its due, if I attempt to localise the very cradle-room of science as the laboratory of the toxicological worker.

Besides snake-poison, the use of animal fluids, either alone or mixed with snake-poison, with which to charge arrows, is pre-historic. Thus in old Greek legend we read how Hercules dipped his arrows in the gall of the Lernean Hydra to render the wounds they inflicted incurable and mortal, and how at last Hercules himself was poisoned by his wife's present, the tunic of the Centaur Nessus stained with his poisonous blood, which she vainly hoped might restore her husband's affection, but which only procured for him the frightful agonies and tortures of which he died.

The use of putrid blood as a poisonous agent and the admixture of the snake-poison with blood constitutes a curious history, when regarded in connection with our present views on septicæmia. The toxic activity of putrid

* A Lecture delivered before the Royal Institution of Great Britain March 2, 1888.

animal fluids seems to have been recognised in very early times. And I suppose these early observations on the effects of putrid blood explain the view almost universally adopted, that blood itself was a poison. Thus the deaths of Psammetichus, king of Egypt (as recorded by Herodotus), and of Themistocles (as recorded by Plutarch), were said to have been effected by the administration of bullock's blood. Even Blumenbach, so lately as the middle of the last century, persuaded one of his class (by way of settling the question) to drink seven ounces of warm bullock's blood. The young man (good as were his intentions) did not die a martyr to science.

The history of poisons and poisoning, the contents of the first chapter of which I have thus briefly indicated (viz., the toxicity of the snake-poison and of blood), down to the final chapter, which commences with the properties and reactions of arsenic, forms a tempting subject for my lecture to-night. The histories of Circe and Medea—of Livia Drusilla and Locusta—of Tiberius and Nero—of the Borgias—of Hieronyma Spara, Tofana, Catherine de Medicis, St. Croix, and a host of other worthies, have proved charming topics for the marvellous-monger. And it would not have been an unworthy subject to bare the truths underlying the stories of generations of storytellers, obscured as they have become by the demand of ignorant sensationalism and the terrors of a mean superstition. But this is not the subject I have proposed to myself for the discourse to-night.

"WHAT IS A POISON?"

Two difficulties present themselves in answering this question:—

1. *The law has not defined a poison, notwithstanding that the law at times demands of science the definition of a poison.*

I know a case, for example, where a prisoner, indicted for the administration of a poison, escaped, because the scientific witness declined to say that the drug administered by the prisoner was a poison.

2. *The popular definition of a poison is far from being a sound, much less a scientific definition.* Generally speaking it comes to this, that "A poison is a drug that kills rapidly when administered in a small quantity."

The phrase "a small quantity" as regards weight, and the word "rapidly" as regards time, are as indefinite as the classical piece of chalk as regards size.

I define a poison as—

"Any substance which otherwise than by the agency of heat or electricity is capable of destroying life either by chemical action on the tissues of the living body, or by physiological action after absorption into the living system."

(A) It will be convenient to consider first, *What a poison is not.*

It is not an agent that destroys life by physical influences, such as heat and electricity.

It is not an agent that destroys life by any purely mechanical act (e.g., pins are not poison, although fairly included in the phrase "destructive things").

It is not an agent that destroys life by the mere blocking out of that which is necessary to maintain life (i.e., the action of a substance to be a poison must be more than mechanical).

This latter point requires further consideration:—

Both nitrogen and carbonic acid destroy life as certainly as they extinguish a burning taper. Yet nitrogen is not a poison, whilst carbonic acid is.

Nitrogen simply destroys life by blocking out oxygen. Given the presence of 20 per cent of oxygen, the 80 per cent of nitrogen possesses no toxic effect.

The carbonic acid, on the contrary, is specifically toxic. The admixture of 20 per cent or of 80 per cent of oxygen does not materially alter the case. Oxygen or no oxygen, CO₂ is a poison.

(B) Consider next, *What a poison is.*

It is an agent capable of destroying life.

The use of the phrase *deadly* poison, is surplusage. If a body be a poison, it is deadly; if it be not deadly, it is not a poison.

My definition limits the mechanism whereby the toxic effect is induced, to *chemical* and *physiological* actions. I am conscious that this definition suggests classification. Certain is it, that Nature hates classification as truly as she declines definitions.

Let us trace some of these mechanisms of toxic activity. I select three illustrations of poisons belonging to different classes.

(1) *Sulphuric Acid.*—If a person swallows sulphuric acid, the tissues with which the acid comes in contact are more or less charred; "more or less," that is, according to the strength of the acid and the time of contact.

Charred.—This implies a chemical act, dependent on the power of sulphuric acid to combine with water.

The portion of the body thus charred dies. We call this *molecular* death. (This does not imply that the person is dead. Health is disturbed. Health is derived from the old Saxon word "Wholth," signifying *entirety*. Health implies the perfect rhythmicity of the bodily functions. It is that condition expressed with charming simplicity by Suffolk folk, who describe being "quite well" by the phrase, "*they feel all over alike*." The charring process (molecular death) has disturbed rhythmicity. Before long all the members suffer with the charred stomach. The death, localised in the first instance, becomes general, the death of the entire body, i.e. of the person, eventually taking place. We call that *somatic* death. This is poisoning by sulphuric acid. But the primary act of disturbance—the first interference with the rhythmicity of health—resulted from the chemical power of sulphuric acid to combine with water. It will be evident that the chemical action of a poison depends on the chemical relationships of that poison.

(2) *Carbonic Oxide.*—Carbonic oxide is a true poison. It is a gas that may often be seen burning with a blue flame on the top of a bright fire in the open fire-stove.

Its importance amongst poisonous bodies depends on the circumstance that it is evolved in many manufacturing operations (e.g. lime and brick kilns, iron blast-furnaces, copper-refining furnaces, &c.), and that it is always present in small quantity in coal-gas, constituting its true toxic constituent.

What, then, is the mechanism whereby carbonic oxide destroys life?—The active agent of the blood is its red colouring-matter (*Hæmoglobin*). To the chemist this substance abounds in wonder.

We have reason to believe that hæmoglobin is formed from the albumenoids, the synthesis of which albumenoids is limited to the vegetable. Essential as the albumenoids are to animal life, the animal is dependent for their formation on the synthetical processes taking place in the plant laboratory. The animal, however, can transmute one albumenoid into another, (e.g. he can change albumen into a peptone), whilst he can also form from them bodies of less complicated constitution (e.g. fat):—in other words he can lower them in the scale. But, save with one exception, he cannot use them to effect higher synthetical formations. This single exception is hæmoglobin.

It is no matter for surprise that a body like hæmoglobin—one of the chief actors, so to speak, in the curious drama of life and living—which comes on the scene through a stage opening, of which we neither know construction nor whereabouts—should possess unique chemical properties and relationships. I shall only trouble you this evening with one of these relationships.

As a general rule, a substance that combines with oxygen with difficulty, parts from it with ease, and *vice versa*. It is difficult to make gold combine with oxygen, but it is easy to decompose oxide of gold. Potassium easily combines with oxygen, but it required the genius of a Davy and the resources of the Royal Institution to separate potassium and oxygen.

In hæmoglobin, however, we have a substance that combines with and delivers up its oxygen (*i.e.* is oxidised and reduced) with almost equal facility under similar conditions. Upon this and other chemical characteristics of hæmoglobin—as the oxygen-receiver, the oxygen-carrier, the oxygen-deliverer, the carbonic acid-receiver, carrier, and deliverer—the act of living depends. In other words, life depends on the *integrity* of the hæmoglobin—on the rhythmicity of those chemical processes, in effecting which hæmoglobin is the primary worker.

With these facts before us, let us turn to the toxic action of carbonic oxide.

The hæmoglobin at once seizes upon and combines with the carbonic oxide, carbonic oxide-hæmoglobin being formed.

Two difficulties arise:—

1. The hæmoglobin, saturated with carbonic oxide, cannot combine with oxygen. Regarding hæmoglobin as a *common carrier*, the carriage is full.

2. The hæmoglobin, being saturated with carbonic oxide, cannot get rid of the carbonic oxide under the ordinary conditions of respiration and circulation. Again, regarding the hæmoglobin as a *common carrier*, the vehicle, full up, cannot be unloaded.

To put all this in scientific phraseology, carbonic oxide-hæmoglobin is a comparatively stable compound, being neither decomposed by the presence of an excess of oxygen (as in the lungs) nor by carbonic acid. What must happen? The man dies because the integrity of the hæmoglobin has been disturbed—because the normal sequence of its oxidation and reduction has been interrupted by the formation of carbonic oxide hæmoglobin.

We call the result of all these chemical actions and interferences, poisoning by carbonic oxide.

3. *Strychnine* (the poison derived from St. Ignatius's Bean).

How does strychnine act? We know sadly little about it—so little that we use the phrase “physiological action” to express our want of knowledge. But we know something.

A marked chemical characteristic of strychnine is its power to combine with oxygen when the oxygen is presented to it in a nascent form.

Note then the conditions. Strychnine is in the body. There is also present in the blood hæmoglobin loosely combined with oxygen, which oxygen the hæmoglobin is always ready to give up on first demand. We are able to trace this action, and to see that the period of the primary strychnine fit coincides with the reduction of the hæmoglobin.

Why (you ask) does that kill? I cannot tell you. It is the highest form of knowledge to see the limits of positive knowledge, and to make that the starting-point for fresh inquiry.

From what I have said, it will be evident that my object has been to trace toxic energy to the chemical action of poisons on living tissues or fluids. The phrase “physiological action” must not be understood as implying any theory *re modus operandi*. There is a danger lest the phrase “physiological action” should be employed, or regarded, as explanatory. It no more explains (be it remembered) the action of certain drugs on the living body than the word catalysis explains fermentation.

(To be continued).

Physiological Researches on an Organic Substance Hydrogenising Sulphur in the Cold.—J. de Rey-Pailhade.—The substance in question (philothion) is obtained from the yeast-cell. It exists in the white of fresh eggs and in the recent blood of sheep. Normal human urine does not contain it. This is the first instance of a compound extracted from a living organism which is capable of hydrogenising sulphur.—*Comptes Rendus*, Vol. cvii., No. 1.

NOTICES OF BOOKS.

Electricity for Public Schools and Colleges. By W. LARDEN, M.A. London: Longmans, Green, and Co.

ELEMENTARY works on electricity and its applications are multiplying in our midst. But the treatise before us presents certain features which should, in our opinion, secure for it a favourable reception. Though intended for use in public schools it is not pervaded by the haunting consciousness of examinations which the pupil must be made, at all hazards, to pass. The book is not “syllabus” ridden. The author's plan of referring the student to special text-books in all parts of the subject where an elementary knowledge of chemistry is required is commendable, as is also his determination to take a different course concerning such a knowledge of systems of units and of mechanical principles, since, as he very justly observes, it is far from easy for the student to collect from various sources just the kind of mechanical knowledge required for the present purpose.

Mr. Larden does not, like some writers who might be named, pass with unbecoming haste from a meagre consideration of general principles to the construction of the dynamo, and then make a neck-or-nothing leap to the telephone. Here, on the contrary, the author expands, though of course in a summary manner, the entire subject—the laws and the facts from which such laws are induced. On this reason we should recommend the present volume as a “first book” on electricity to anyone who hoped in the future to turn his attention, more or less, to electric or magnetic research. There is no attempt at enumerating and describing all the various batteries, dynamos, &c., which have been devised by inventors. Neither do we find any discussion on the questions of priority which spring up in electricity more, perhaps, than in other sciences, and which occasion great trouble in Courts of Law. Such considerations are obviously of no use to the student. Another commendable feature is that mathematical formulæ, though introduced where useful, are not employed where they might be dispensed with.

The bibliography which follows upon the preface, though the author admits its incompleteness, will prove exceedingly useful to pupils who wish to push their studies further in any department.

The arrangement of the work is as follows:—After stating the general phenomena of magnetism the author passes on to the mechanical and magnetic units, magnetic measurements, and terrestrial magnetism, the simpler phenomena of electrostatics, potentials, the elementary consideration of condensers, induction machines, atmospheric electricity, specific inductive capacities, electrostatic potential, the phenomena of currents and their accompanying phenomena, Ohm's law, the measurement of resistance and of electromotive force, Joule's law and the conservation of energy, galvanometers, action of currents on magnetic poles, selenoids, electro-magnets and diamagnetism, electro-magnetic induction, Ruhmkorff's coil, dynamo-machines, and various applications of electricity.

It will thus be seen that Mr. Larden gives a broad, comprehensive view of the science, whilst we think any careful reader will be satisfied with the expositions given.

The Retrospect of Medicine: being a Half-yearly Journal containing a Retrospective View of every Discovery and Practical Improvement in the Medical Sciences. Edited by JAMES BRAITHWAITE, M.D. (Lond.). Vol. xcvi., January—June, 1888. London: Simpkin and Marshall.

A VERY interesting paper in this issue is the one by Dr. G. Johnson on albuminuria as a result of sewage poisoning. The author gives four cases distinctly traceable to this cause, or, to speak more guardedly, cases where sewage poison must have been actually present, whilst, at the

same time, no other cause for the disease could be discovered. Dr. Johnson considers that sewage-poisoning is by no means an infrequent cause of blood-poisoning and consequent albuminuria, and that where it occurs the possibility of sewer-poisoning should always be borne in mind by the medical adviser. It is important to learn that the evil effects of sanitary neglect are not confined to epidemics of acute diseases.

Mr. Jonathan Hutchinson calls attention to the prolonged internal use of arsenic as a possible cause of cancer. Now the employment of arsenic as a cosmetic is recognised as an indisputable fact this danger should be brought under public notice.

It is further interesting to learn that "antipyrine," which is now becoming a fashionable panacea, is not without danger, even in the hands of experienced physicians. Dr. Jennings, of Paris, describes here certain cases of its alarming results.

Applications of Dynamics to Physics and Chemistry. By J. J. THOMSON, M.A., F.R.S., Cavendish Professor of Experimental Physics, Cambridge. London: Macmillan and Co.

"LET none save mathematicians enter here" is said to have been the motto fixed up by a Greek philosopher of old over the entrance to his school. Professor Thomson might very fittingly have placed a similar caution on his title-page. To the majority of chemists this book will be purely unintelligible, and not a few physicists—we think Faraday, were he still alive, might be included—will fare but little better. We submit that an attempt might at least have been made to state definitely in language—and not merely in formulæ—what the author is aiming at and what results he has established.

The chemical subjects discussed are evaporation, the properties of dilute solutions, dissociation, the general case of chemical equilibrium, the effects produced by alterations in the physical conditions on the coefficient of chemical combination, the change of state from solid to liquid, and the connection between electromotive force and chemical change.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 1, July 2, 1888.

Application of Carnot's Principle to Endothermic Reactions.—M. Pellat.—The higher the temperature of a source of heat the further its spectrum extends on the ultra-violet side. We remark that certain endothermic reactions can be effected by very refrangible radiations, though they cannot be produced by the less refrangible radiations, though they cannot be produced by the less refrangible radiations because such may be emitted by sources of heat of a lower temperature.

Certain Compounds of the Cerite Metals.—M. Ouvrard.—The author seeks to obtain new salts of cerium, lanthanum, and didymium by acting upon the oxides of the metals with alkaline phosphates. The cerium oxide was completely freed from lanthanum and didymium by fusing the nitrates in ten times their weight of saltpetre. Lanthanum oxide, separated from didymium by Marignac's method, was free from cerium, and its concentrated nitric solution did not present the absorption-bands of didymium. After ignition in the air lanthanum oxide remained perfectly white. Cerium and lanthanum yield, by the re-

actions employed, products absolutely identical in crystalline form and chemical composition, differing merely in colour. The didymium oxide employed was free from lanthanum, but it had not been treated for the separation of other oxides which it might contain, such as samarium. Its equivalent was very close upon that given by M. Cléve for pure didymium (71). Didymium behaves with the potassium phosphates like those of cerium and lanthanum, giving under approximate conditions either tribasic didymium phosphate or a double phosphate.

On Cuprous Chloride Hydrochlorate.—Paul Sabatier.—The writer admits the priority of M. Engel (*Comptes Rendus*, cvi., p. 273). He assigns, however, to this compound the formula $\text{CuCl}_2 \cdot 2\text{HCl} \cdot 5\text{H}_2\text{O}$, whilst M. Engel regards the compound as $\text{CuCl}_2 \cdot \text{HCl} \cdot 3\text{H}_2\text{O}$.

On Cobalt Chloride Hydrochlorate.—Paul Sabatier.—Cobalt chloride is precipitated from its saturated aqueous solution by the addition of hydrochloric acid. Inferior hydrates may be obtained, but when the proportion of acid increases more and more the solubility of the salt does not always decrease, but passes a minimum, like copper chloride. The author has not been able to determine the composition of the pulverulent pale blue hydrochlorate, which decomposes on drying, leaving the amethyst-coloured chloride.

Contribution to the Means proposed for the Sanitation of Towns.—P. Chastaing and E. Barillot.—The authors state that for the treatment of sewage, &c., two systems are in actual use:—(1) *Irrigation or purification by the soil and by cultivation*, a system having many partisans, applicable when immense surfaces are available, when the ground is suitable for this kind of treatment, and when the water to be purified is not highly charged with putrescible matter; (2) *the chemical processes*, much denounced for some years, though, in virtue of the improvements recently effected and still possible, they merit the greatest attention. The authors conclude from their experiments:—(1) That the purification of sewage by the chemical method has a real efficacy; (2) that it may be applied without interruption and without insalubrious emanations; (3) that the agricultural utilisation of the nitrogen, potash, and phosphoric acid of the sewage is easily realised by this method.

Bulletin de la Société Chimique de Paris.
Vol. xlix., No. 8.

On the Iodophenols.—E. Noeltling and Th. Strecker.—The authors have prepared the ortho-, meta-, and para-iodophenols in a state of purity, and furnish an account of their properties.

Action of Roasting upon Various Oxides and Salts of Manganese.—A. Gorgen.—The oxidation of anhydrous manganese monoxide in contact with air may be continued up to the dioxide or may be stopped at the terms $3\text{MnO}_2 \cdot \text{MnO}$; $\text{MnO}_2 \cdot 2\text{MnO}$; $\text{MnO}_2 \cdot \text{MnO}$. The red oxides can in general be oxidised by roasting. Manganese sesquioxide obtained below 300° is capable of observing oxygen from the air, and may be converted into dioxide by roasting. The manganese salts capable of yielding monoxide when ignited in the absence of air produce, after roasting, various peroxides, according to the circumstances in each case.

On a New Oxy-acid of Sulphur.—M. Villiers.—By the action of sulphurous acid upon sodium hyposulphite the author obtains the sodium salt of a new acid, $\text{S}_4\text{O}_8\text{Na}$.

On Saccharomyces Ellipsoideus and its Industrial Applications in the Manufacture of a Wine from Barley.—George Jacquemin.—The ferment of wine which has been used in the author's experiments for eighteen months has presented the greatest stability, and constitutes a species of ferment perfectly distinct from beer-yeast.

Researches on the Sulphines.—G. Patein.—The author has obtained four sulphine iodides, and is now about studying the corresponding cyanides.

A Novel Process for Preparing Tetraphenyl-ethylene.—Pierre de Boissieu.—It has been previously shown that the bromo-derivatives of diphenyl-methane are partially decomposed on dry distillation. From the decomposition of mono-bromo-diphenyl-methane they have, in this manner, obtained tetraphenyl-ethylene.

Extraction of Lead from the Residues of the Production of Zinc.—Eugene Prost.—The residues can be mechanically separated into two classes: "fine cinder," containing from 15 to 22 per cent of lead, and "granules," which do not contain more than 10 per cent. Both contain silver to the extent of from 225 to 340 grms. per ton. The author has succeeded in extracting from 84 to 90 per cent of the lead present.

The Industrial Value of Thompson's Calorimeter.—M. Scheurer-Kestner.—The author shows that this instrument may furnish indications useful to practical men who merely wish for an approximate result. In experienced hands the maximum error does not reach 4 per cent.

The Spectroscopic Detection of Blood.—G. Linossier.—The author considers that even when the spectra of oxy-hæmoglobine and of reduced hæmoglobine have been observed it is prudent to look for a confirmation in the spectrum of reduced hæmatine, since we are not yet fully acquainted with the spectroscopic characters of the innumerable artificial colouring-matters which industry is daily creating.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 1.

The Quantity of Moisture which Remains in a Gas after Desiccation by Phosphorus Pentoxide.—E. W. Morley.—Dibbitts has previously shown how much moisture remains unabsorbed by calcium chloride at different temperatures. Sulphuric acid leaves approximately $\frac{1}{4}$ m.grm. of moisture in 100 litres of air. The author finds that the proportion of moisture not absorbed by phosphorus pentoxide is only $\frac{1}{4}$ m.grm. in 1000 litres of gas.

Improvement in the Goldenberg Method for the Analysis of Materials containing Tartaric Acid.—Dr. N. v. Lorenz.—Fifteen grms. tartar or lees of wine (7.5 grms. tartrate of lime) are comminuted as finely as possible and mixed with 250 c.c. (or respectively 150 c.c.) of water and 6 grms. of dry potassium chlorate in a porcelain capsule, holding at least 700 c.c., and boiled for twenty minutes over an open fire, stirring well and replacing the water lost by evaporation. When cold, the entire contents of the capsule are rinsed into a flask holding 500 c.c. (respectively 250 c.c.), and filled up to the mark. After it has been well shaken up it is filtered through a dry folded filter into a dry glass; 100 c.c. of the filtrate are then evaporated in a porcelain capsule of the size above mentioned on the water-bath until saline matter is just on the point of being deposited. The con-

tents of the capsule, while still warm, are mixed with 5 c.c. glacial acetic acid, stirred until all the carbonic acid is expelled, after the lapse of five minutes mixed with 100 c.c. absolute alcohol, and stirred for two minutes. After fifteen minutes it is filtered through a filter holding 50 c.c., using, in preference, the filter-pump. The capsule is then washed with absolute alcohol until the filter is filled with the rinsings, using about 50 c.c. of alcohol. The margin of the filter is then twice washed with absolute alcohol, using each time 25 c.c. and letting the liquid drain thoroughly away. The filter with its contents is then returned to the precipitation-capsule, covered with 200 c.c. of water, heated to a boil, and titrated as follows with soda-lye, which must not be stronger than 0.3-normal. The hot liquid is mixed with neutral tincture of litmus, and the lye is then let run in until the bright red becomes decidedly dark red. It is then boiled for five minutes until the margin of the liquid has lost its violet cast and become a dead blue. The lye consumed is calculated for 3 grms. of the original substance. The alkaline lye is standardised by means of a tartar obtained from Seignette's salt and hydrochloric acid after repeated crystallisation from hot water.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1496.

NOTE ON THE ACTION OF PETROLEUM ON LEAD.

By WILLIAM FOX.

WHEN petroleum is stored in lead-lined tanks the lead is rapidly corroded, a heavy brownish-coloured powder being formed. Tanks in constant use, built of concrete and lined with heavy sheet lead, used for the storage of petroleum, become worn out in about three years owing to this corrosion. On analysis the powder from one of these storage tanks was found to consist of carbonate and hydrated oxide of lead and a small quantity of valerate of lead; the brownish colour was due to organic matter.

It appears probable that the white lead, of which the powder practically consists, and a paraffin, is formed by the action of an oxidising agent and a small quantity of valeric acid present in the petroleum on the lead, which may be expressed by the formula:—

a view supported by the following experiments:—

I. Petroleum free from acidity, sealed in a tube with lead and heated in the water-oven some time, formed oxide of lead, but no hydrated oxide or carbonate of lead, nor was any gas evolved.

II. Valeric acid, sealed in a tube with lead and oxygen and heated in the water-oven, gave a white compound which proved to be carbonate and hydrated oxide of lead; the oxygen was absorbed.

III. Petroleum free from acidity, sealed in a tube from which oxygen was carefully excluded, with a small quantity of valeric acid and lead, gave hydrated oxide and carbonate of lead.

Laboratory, 4, Great Tower Street, E.C.

NOTE ON SOME NEW SALTS OF PHENYL-HYDRAZINE.

By W. H. RICHARDSON.

DURING some experiments made with the idea of throwing light on the constitution of the beta-naphthol-azo compounds I examined the behaviour of oxy-azo-naphthalene and its sulphonic acid towards phenyl-hydrazine. I found that the sulphonic acid (roccelline) reacts readily, a new well-characterised substance being formed. This new body I was at first inclined to regard as a hydrazide, assuming that Liebermann's formula for the azo-derivatives of beta-naphthol is a correct one. Later on I found, however, that most sulphonic acids of oxy-azo-compounds react with phenyl-hydrazine, and that the presence of the beta-naphthol rest is not essential to the production of these compounds. From their properties I am inclined to regard them as simply hydrazine salts of the respective sulphonic acids; they may, however, be molecular compounds, similar in constitution to the bisulphite compounds of the azo-dyes described by Spiegler.

The compound from roccelline may be described in detail.

It is obtained by adding an aqueous solution of phenyl-hydrazine hydrochloride to a solution of roccelline acidified with hydrochloric acid. On acidifying a solution of roc-

celline a brown flocculent precipitate of free oxy-azo-naphthalene sulphonic acid separates, and this, on adding the hydrazine, becomes scarlet and crystalline. The yield is quantitative.

For analysis the substance was crystallised from dilute alcohol.

Sulphur Estimation.

I. 0.180 grm. gave 0.0905 grm. BaSO₄.

II. 0.231 " " 0.112 " "

I. II.

S 6.8 per cent 6.6 per cent

Calculated for a molecular compound or a salt of phenyl-hydrazine and oxy-azo-naphthalene sulphonic acid, S 6.5 per cent.

The numbers above do not suffice to determine whether the compound is a salt or a hydrazide, the latter giving 6.8 per cent of sulphur.

The preparation of metallic salts by double decomposition has, however, rendered the assumption that the compound is a salt very probable. The barium, calcium, and magnesium salts were prepared, and found qualitatively to contain no hydrazine. In addition to this the barium salt was prepared by different methods, and barium estimations made. The numbers obtained show that the salt is oxy-azo-naphthalene sulphonate of barium and not the barium salt of a hydrazide.

I. Barium salt obtained by precipitation of a dilute alcoholic solution of the re-crystallised substance with barium chloride.

II. Barium salt obtained from the aqueous solution of the re-crystallised substance.

III. Barium salt from an aqueous solution of the product.

	I.	II.	III.
Barium found	14.95	15.12	15.01

Calculated for oxy-azo-naphthalene-barium sulphonate, barium = 15.4 per cent, while the barium salt of a hydrazide would give 12.7 per cent barium.

The properties of the compound itself are not of great interest. It is easily decomposed by boiling dilute acids or alkalis. It is sparingly soluble in water, easily in alcohol or acetic acid.

The corresponding hydrazine salts of several other azo-dyes have been prepared, but do not require any detailed description.

Through an error I made some experiments with naphthol yellow S, supposing it to be an azo-dye, as the name my sample went under is the name usually ascribed to amido-azo-benzene sulphonic acid. I found, however, that in this case, also, phenyl-hydrazine forms a characteristic salt, which is sparingly soluble in boiling water and crystallising from that medium in pretty light brown needles.

The formation of this compound will perhaps serve as a method of distinguishing between naphthol yellow and other yellow dye-stuffs. A solution of 1 grm. of the dye in a litre of water gives a crystalline precipitate on adding phenyl-hydrazine hydrochloride dissolved in water after a few minutes. The formation of the precipitate may be hastened by scratching the sides of the vessel with a glass rod.

In order to determine the composition of the body a sulphur estimation was made. The result shows that the compound is a phenyl-hydrazine salt of dinitro-alpha-naphthol sulphonic acid of the formula—

Calculated. Found.

S 7.5 per cent 7.8 per cent.

I may say, in conclusion, that the roccelline and naphthol yellow S used in these experiments were converted

into barium salts, and barium estimations made, in order to make sure that the dye-stuffs were pure.

Southowram, Halifax,
July 5, 1888.

TESTS FOR NITROUS ACID BASED ON MODIFICATIONS OF THE SULPHANILIC ACID METHOD OF GRIESS.

By DAVID LINDO.

OF the tests for nitrous acid discovered by Griess, one depends on reaction between the acid and metaphenylenediamine; some of the phenols reacting with the acid under similar conditions yield coloured products, *α*-naphthol for example, as mentioned under the head of "Notes," in a former paper, and I have since found the colour becomes more intense if the solution is rendered alkaline some time after adding the other reagents. Orcinol, I observe, also gives a colour reaction, but it is deficient in delicacy. It does not appear that the number of really good tests for nitrites is likely to be greatly increased in this direction; the contrary, however, is the case when sulphanic acid is introduced, which is one of the reagents used to produce Griess's wonderfully delicate reaction. The other, it is well known, is naphthylamine, and the reaction occurs in an acidulated solution, the proper medium when naphthylamine is employed.

It appears a most important modification of the sulphanic method was introduced last year by Zambelli, but this only came under my notice quite recently through reference made to it in a paper by Professor P. F. Frankland, on a "Gasometric Method of Determining Nitrous Acid."* Frankland says:—"Zambelli adds to the solution containing the nitrite a drop of a saturated solution of sulphanic acid, then a drop of an aqueous solution of phenol, the mixture being then rendered alkaline with ammonia; the presence of nitrous acid is indicated by the appearance of a colouration, varying from faint yellow to intense reddish-yellow (like the colour of a strong solution of potassium dichromate), according to the quantity of the nitrous acid present."

When I met with this reference, having solutions of pure nitrite, carbolic acid, and several other phenols ready prepared, it naturally occurred to me to try all the phenols at hand in succession, which was done with the following results:—

Carbolic Acid.—Zambelli's observation confirmed.

Thymol.—Excellent reaction, stronger colour than carbolic gave at the same dilution of N_2O_3 (1,000,000), and inclined to orange.

Orcinol.—Reaction quite as good as with carbolic acid.

***α*-Naphthol.**—Pink to red, according to strength of N_2O_3 solution.

I have since referred to abstract of Zambelli's paper, which appeared in the *Journal of the Chemical Society* last year, and find he employed *α*-naphthol and got the same result as I obtained with it. I used 1 per cent alcoholic solution of this phenol.

Previous to referring to the abstract, I had used a saturated aqueous solution of sulphanic acid and 1:5 sulphuric. Zambelli dissolves the sulphanic in dilute sulphuric, which of course is more convenient. I had found it indispensable to let the tests rest a few minutes after adding everything but the ammonia, before the latter was introduced, otherwise very little colour will be developed, even with pretty strong solution of nitrite. Zambelli, I observe, recommends an interval of ten minutes, which, at the temperature I worked at (about 28° C.) was found even more than sufficient. Provided the nitrous acid is allowed to act long enough on the sulphanic, before adding the ammonia, it does not appear

to matter whether the phenol is added immediately after the sulphanic, or just before the ammonia.

These phenols give no colour reactions (or only feeble ones) with nitrous and sulphanic acids in acid solutions. The prominent feature, therefore, in Zambelli's modification of the sulphanic method is making the solution alkaline* after adding the other reagents, thereby rendering several phenols available as highly delicate and characteristic tests for nitrous acid, which would otherwise be of little or no value for the purpose. *α*-Naphthol, indeed, becomes a fairly good reagent when the solution is made alkaline, even without the intervention of sulphanic acid; the colour, as already stated, is yellow, whereas, with the addition of sulphanic, it is red. As regards orcinol, this of course is not a reliable agent at very high dilutions of N_2O_3 , since solutions of this phenol, as it is very well known, gradually acquire colour on exposure to air in presence of alkalies, especially in the presence of ammonia.

The delicacy of the thymol reaction has been tested; comparative tests with carbolic acid were made at the same time.

Reagents.

Carbolic Acid.—10 per cent solution in dilute alcohol.

Thymol.—10 per cent alcoholic solution.

Sulphanic Reagent.—1:5 sulphuric saturated with sulphanic acid.

Ammonia.—6 to 7 per cent solution of ammonia.

Method.

Five c.c. nitrite solution taken for each test, $\frac{1}{8}$ -inch test-tubes employed. Three tests with each phenol made at each dilution of nitrite. Added to the solution to be tested, 1 drop of the sulphanic reagent, and 1 drop phenol or thymol solution; let rest ten minutes, then added 1 c.c. ammonia, and mixed well.†

I have stated above that at 1,000,000 N_2O_3 the colour is deeper with thymol than with carbolic acid; with stronger solutions of nitrite, say 100,000 N_2O_3 , the contrast is very great. There is this difference, however, between the colours which may cause phenol to be preferred for quantitative work. At 1,000,000 N_2O_3 , and even before this dilution is reached, carbolic acid yields a bright pronounced yellow colour, whereas thymol—even at the highest dilutions of N_2O_3 —gives a colour with a tinge of orange in it, never a definite yellow. The limit for both tests, using five c.c. of nitrite solution, seems to be about 1 N_2O_3 in 10,000,000 of water, the colours being very weak at this dilution.

The colours are fully developed immediately, or almost immediately, after adding the alkali,—a great point in favour of Zambelli's modification, especially when the method is used as a quantitative test. Another point in its favour is that the solutions are stable; Frankland has called attention to this, referring to carbolic acid: the same advantage attends the use of thymol.

I have only seen the abstract of Zambelli's paper. It is quite possible that in the original he has anticipated me in some of the observations I have made respecting the other phenols.

The Test Reversed.

These reactions can be made available for detecting very minute traces of the phenols in aqueous solution, but it will be seen at once they possess the defect in a high degree which is common to many of the tests already known, viz., that of not being characteristic. Carbolic acid and orcinol, it has been shown, give a yellow colour with the reagents at high dilutions, and no doubt there are several other phenols and allied bodies that will do the same. Thymol gives an orange even at high dilutions, but might easily be mistaken for a stronger solution of

* Pure fixed alkalies may be used, but ammonia is more convenient.

† Blank tests with distilled water and the reagents were of course made at the same time.

carbolic or orcinol. It is even doubtful if the red colour given by α -naphthol is peculiar to this phenol. Nevertheless, in consequence of their extreme delicacy, these reactions may under certain conditions prove of some value.

A mixture of pure nitrite solution ($2000 \text{ N}_2\text{O}_3$) and the sulphanilic reagent, in equal volumes, was made, and allowed to stand a few minutes before it was used. This mixed reagent developed a yellow colour when ammonia was added to some of it in the undiluted state; but when 1 drop was mixed with 5 c.c. distilled water, and 1 c.c. of dilute ammonia added, no colour was observed. One part of carbolic acid in 1,000,000 parts of distilled water gave a very distinct yellow colour; with 1 drop of reagent and 1 c.c. ammonia, 5 c.c. of the phenol solution being used, α -naphthol at the same dilution—tested in the same way—gave a very distinct pink colour. This is certainly, as far as I am aware, a much smaller proportion of carbolic acid than any test on record is capable of detecting; but on the other hand, even with no more knowledge than we already possess of the action of the reagents on other bodies, we must pronounce this test to be very unreliable.

NEW METHODS FOR THE ESTIMATION OF SULPHUR IN STEEL AND STEEL-MAKING IRON.

By J. O. ARNOLD and HENRY J. HARDY.

THERE is a general consensus of opinion amongst analysts that the sulphur present in steel or iron is most accurately determined by ultimately weighing it in the form of barium sulphate. The preliminary operations by means of which the sulphur is obtained in a state suitable for precipitation vary somewhat with different operators, but they all resemble one or other of the two following methods in general procedure.

Aqua Regia Process.

In this method the steel is dissolved in nitro-hydrochloric acid, and the resulting solution is evaporated to dryness to render the silica insoluble. The dry mass containing the sulphate of iron is taken up in hydrochloric acid, the excess of the latter necessarily used being evaporated off, until only sufficient to retain the iron in clear solution is present. The concentrated liquid is then diluted and the insoluble residue is removed by filtration. The filtrate is next largely diluted and the sulphur is precipitated by means of barium chloride.

Evolution Method.

In this process the steel is attacked by a non-oxidising acid (dilute sulphuric or hydrochloric) and the evolved H_2S is absorbed in an oxidising liquid, such as bromine water or potassium permanganate solution. After removal of the excess of bromine or decomposition of the surplus permanganate, as the case may be, the sulphur is precipitated by barium chloride from a faintly hydrochloric acid solution.

In addition to methods such as the above, Eggertz has proposed a colorimetric process in which the sulphur present in the iron is approximately estimated by the intensity of colour produced on a silver plate by the evolved H_2S . Wiborgh has proposed a modification of the last method, in which cloth, saturated with cadmium nitrate is substituted for the silver plate.

Morgan (CHEMICAL NEWS, vol. lvi., p. 83) proposed to pass the gases evolved on treating 0.5 gm. of steel with dilute sulphuric acid into 50 c.c. of a dilute solution of lead acetate, and comparing the colour so produced with those obtained by treating in a similar manner steels standardised by the barium chloride method.

The author's experience of this process is that under the prescribed conditions the "colour" obtained (say from a steel containing 0.05 per cent S) is a very decided precipitate, and that consequently accurate comparison is impossible.

The process generally used in the laboratories of iron and steel works is the aqua regia method, and its almost universal adoption is no doubt justified by the accurate results yielded by carefully carried out estimations. But it is nevertheless anything but an ideal process, for several reasons.

1. The gases evolved during the solution of the steel are very irritating and injurious.

2. The sulphur in the reagents used during the analysis must be carefully estimated and the "blank" so obtained must be deducted from the gross weights.

3. Any appreciable amounts of acid over and above that necessary to retain the iron in solution causes the method to yield low results, and the exact point is not very easy to hit, and, if over-stepped, causes a precipitation of the iron.

4. The time occupied in making an estimation is about two days, twenty-four hours being usually allowed for the precipitation alone.

5. The barium sulphate obtained is sometimes difficult to filter; it is also occasionally impure with iron, and the removal of the latter with hydrochloric acid may entail loss. The dubious expedient sometimes recommended for the purification of the precipitate, namely, fusion with sodium carbonate and re-precipitation, seriously increases the length of an already tedious process.

The inconveniences enumerated above induced the authors to try and devise a rapid and accurate method for the estimation of sulphur in steel, and after many failures they have succeeded in elaborating two processes, one colorimetric and approximate, but very rapid, occupying only twenty minutes, the other volumetric and exceedingly accurate, occupying about an hour and three-quarters, or, if the estimation is made in duplicate, two hours and a half.

Both these methods are based on the generally admitted principle that the sulphur in steel or steel-making iron (in which 0.13 per cent may be considered as the maximum amount usually met with) is completely evolved as H_2S on heating the finely-divided metal (in small drillings) with dilute sulphuric acid (1 in 7). The authors have confirmed the accuracy of the above enunciation by numerous experiments.

Method I.

The apparatus employed in this process is represented in Fig. 1. 0.2 gm. of the steel is weighed out into the flask, A, which has a capacity of about 200 c.c. With the steel are placed a few small pieces of solid stick zinc (chemically pure) and about 20 c.c. of water. The tube, F, which is graduated at 30, 40, and 50 c.c., is about 20 m.m. in diameter and 300 m.m. in length, and contains 30 c.c. of a solution of sodic hydrate, prepared by dissolving 25 grms. of stick soda in a litre of water.

The cylinder, E, which should be graduated, contains dilute sulphuric acid (1 in 4). Both ends of the bent tube, D, are fused up so as to leave openings about the size of an ordinary wash-bottle jet, to prevent the too violent flow of acid. The end of the gas delivery tube, G, is also contracted, to break up the bubbles and facilitate absorption. The parts of the apparatus having been tightly fitted together, the water in A is boiled to expel the air from the apparatus. The india-rubber tube, C, is then closed with a clip, the position of the latter being indicated by the letter in the figure; the lamp is withdrawn and 15 c.c. of acid are allowed to pass into the flask from the cylinder, E, the india-rubber tube, B, being then closed with a clip.

As soon as the evolved hydrogen restores the equilibrium of pressure within the flask (which is indicated by the distension of the collapsed india-rubber connection

tube), the clip, *c*, is opened, when the gases bubble through the soda in *F*, which effectually absorbs the sulphuretted hydrogen. The sand-bath is gently heated until all the steel is dissolved; the more compact pieces of zinc, however, continue to act on the acid, and the evolved hydrogen carries into the soda solution the last traces of H_2S given off from the steel. The action is continued until the contents of the absorption-tube measure, after cooling, 40 c.c.*

To the fluid in the tube next add 10 c.c. of a dilute solution of lead acetate, containing in that volume enough acid to neutralise the soda and render the liquid distinctly acid.† A brown colour, due to the formation of PbS , is thus produced, proportional in intensity to the amount of sulphur present in the steel. Close the mouth of the tube with the hand and gently mix the contents. The percentage of sulphur is next determined by comparing the colour produced with that yielded by standards containing known quantities of PbS . These standards must be prepared in tubes exactly similar to the absorption tube, whilst the solution of the steel is proceeding, and the comparison must be made without loss of time.

The standard solution is prepared by dissolving 0.4725 gm. of pure crystallised acetate of lead in 1000 c.c. of

the sulphur had been carefully determined as barium sulphate, lead the authors to fix the possible errors of this process as follow:—In steels ranging from 0.01 to 0.04 the divergence from the truth will never exceed 0.01 per cent; steels containing 0.06 to 0.1 per cent may yield results as far out as 0.02 per cent; impure steels containing 0.11 to 0.14 per cent occasionally diverge as much as 0.03 per cent. This process is consequently not adapted for cases where rigidly accurate results are required, but often in a steel works the information desired is, whether the material in question is a Swedish steel, containing say 0.01 per cent of sulphur, a high-class English steel, containing say 0.05, or an impure Bessemer steel, containing perhaps 0.1 per cent of sulphur. Such a query is accurately answered by the foregoing method in less than half an hour.

It may be mentioned in connection with this process that efforts have been made to obtain a stable standard sulphide solution, but in this the authors have been unsuccessful. They have also endeavoured to get standard tints, both with anilines and with inorganic salts, such as those of palladium, but all attempts in this direction have ended unsatisfactorily.

Method II.

This process gives results certainly less than 0.01 per cent from the truth, as the authors have carefully proved by comparison with the barium sulphate method. The figures obtained are also remarkably concordant. In one case the sulphur in an English steel was found by barium sulphate to be 0.07 per cent. Seven determinations were then made by the method about to be described, and on each occasion the result was sharply registered as 0.06 per cent, which the authors regard as the truer result. In another case the aqua regia process indicated the sulphur in a Swedish steel to be 0.01 per cent. Four estimations by the new method each gave the same results, namely, 0.01 per cent. A grey hematite iron which had been twice melted in a cupola was found, by the aqua regia process, to contain 0.12 per cent; an estimation by the new method registered the sulphur present as 0.11 per cent. The apparatus used is represented in Fig. 2. *B* is a glass gas-holder, having a capacity of about 5 litres. It contains pure hydrogen,* well washed in sodic hydrate, and when filled holds gas sufficient for two estimations. The flask, *A*, has a capacity of about 250 c.c., and is fitted with an india-rubber cork, in which is inserted a small separator, an exit tube of about 3 m.m. external diameter, and an inlet tube for the hydrogen of about 3 m.m. internal diameter. Weigh out into the flask exactly 2 grms. of the steel in fine drillings and add 20 c.c. of distilled water, adjusting the end of the hydrogen inlet tube so that it dips under the surface, connect the flask with the gas-holder and with the first cylinder on the stand, *E*, part of which, the rack, *D*, is movable,† and contains fifteen tubes about 75 m.m. long by 12 m.m. inside diameter. In each of these cylinders (except the first one, which is left empty to act as a condenser) is placed, by means of a burette, exactly 2 c.c. of an acid solution of lead acetate, made by dissolving 1.812 grms. of crystallised normal acetate of lead, $\text{Pb}(\text{Ac})_2 \cdot 3\text{H}_2\text{O}$, in weak acetic acid and diluting to 1000 c.c. Each tube thus contains a quantity of lead sufficient to fix as sulphide 0.01 per cent of sulphur in 2 grms. of steel.

A full-size sketch of two of the cylinders is shown in Fig. 3; the india-rubber cork is furnished with a straight exit tube 30 m.m. long, and an inlet tube, bulbod about 12 m.m. from the end, the bulb to be about 1 m.m. smaller than the cylinder in diameter. By means of this device a practically perfect absorption is obtained, so that the successive increments of 0.01 per cent of sulphur

FIG. 1.

very dilute acetic acid; each c.c. of this solution thus contains lead equivalent to 0.02 per cent of sulphur in 0.2 gm. of steel.

To No. 1 standard is added 1 c.c., to No. 2, 2 c.c., and so on, advancing by increments of 0.02 per cent of sulphur. The standard tubes are then filled up with water nearly to the 50 c.c. mark, the exact volume in each case being made up with a slight excess of good H_2S water. The contents of each tube are then gently mixed. On comparison it will be readily seen to which standard the steel under examination most closely approximates, the odd hundredths, 0.01, 0.03, &c., being obtained by interpolation.

The results of numerous experiments on steels, in which

* This is best seen by making a mark on the tube, *F*, between the 40 c.c. and 50 c.c. graduations, the exact point depending on the volume occupied by the delivery tube when full of gas, the slight contraction of the liquid on cooling being also taken into account.

† A suitable solution may be made by mixing 300 c.c. of water with 200 c.c. of 35 per cent acid and dissolving in this liquid 1 gm. of $\text{Pb}(\text{Ac})_2 \cdot 3\text{H}_2\text{O}$.

* If air is used instead of hydrogen a small portion of the H_2S is decomposed and the result obtained is slightly low.

† By this arrangement a second rack containing tubes for a duplicate estimation may be prepared whilst the first determination is proceeding.

FIG. 2.

evolved from the steel are sharply separated, none passing a tube until the lead in solution is completely precipitated. When gas is passing the liquid is split into two parts, one

FIG. 3 (Full size).

under and the other above the bulb, so that, in addition to passing through two layers of absorbent, the gas is

also sandwiched for a moment between the two liquid strata. The india-rubber tubing which connects the flask with the cylinders and the cylinders with each other must have a small bore and thick walls to prevent diffusion. The aspirator, c, is graduated in litres.

When all is ready, the air is swept out of the apparatus by forcing and aspirating through it 1 litre of hydrogen; the gas-holder tap is now shut, and 30 c.c. of dilute sulphuric acid (1 in 4) are run into the flask from the separator, the aspirator tap being fully opened. Gentle and intermittent heat is next applied to the sand-bath until the steel or iron is completely dissolved. The rate of the passage of the gas through the cylinders should be slow and regular. When all, or nearly all, action has ceased, the hydrogen tap is again opened and another litre of gas is aspirated through the apparatus.

As the operation above described proceeds, one by one the contents of the cylinders will blacken, each cylinder precipitated representing one-hundredth per cent of sulphur. The termination of the reaction is thus self-indicating, and all that remains to do is to count the precipitated cylinders. A faint colour in the last tube may be ignored, whilst a decisive tint, but still one short of complete precipitation, may be taken as representing only 0.005 per cent if such refinement is deemed necessary. There is no difficulty in deciding this point: the completely precipitated liquid is black-brown, the colour when semi-precipitated being dark ruddy brown, the tint communicated by a trace of H_2S is yellow-brown.*

It would seem at first sight that the appreciable solubility of H_2S in water must seriously affect the accuracy of the process, owing to the liquid in the cylinders nearest the flask retaining in solution H_2S over and above that necessary to precipitate the lead. But the current of hydrogen passed at the termination of the operation effectually carries forward every trace of sulphur until it is fixed by its equivalent of lead. This statement can be readily demonstrated by placing in a cylinder a very dilute solution of H_2S and attaching it to another cylinder containing lead solution. On passing hydrogen from the

* The authors have not yet applied the process to sulphurous irons, but probably by a suitable arrangement of standard solutions (e.g., charging the first two or three cylinders so as to absorb increments of 0.1 per cent), accurate results may be obtained.

sulphide to the lead cylinder, the latter is at once precipitated, and after a little time the first cylinder will prove on testing to be quite free from H_2S .

Another point which has received the authors' careful attention was, whether the co-evolved phosphoretted hydrogen would affect the accuracy of the results. They have proved that such is not the case, and their conclusion may be demonstrated experimentally in the following manner:—Take 2 grms. of a steel containing about 0.05 per cent of sulphur and 0.05 per cent of phosphorus. In each of the first three cylinders of the apparatus already described place lead solution of a strength sufficient to absorb completely the weight of sulphuretted hydrogen which will be evolved from the steel; in the fourth cylinder place a solution of nitrate of silver. On proceeding with the experiment exactly as in the sulphur estimation, the whole of the H_2S will be absorbed in the first tube; the second and third tubes will remain clear, quite unaffected by the phosphoretted hydrogen, which, however, produces a black precipitate in the fourth tube, containing the silver salt. The unfortunate fact that the phosphorus present is not completely evolved as hydride effectually extinguishes any attempt to apply the apparatus to the quantitative determination of phosphorus.

The authors considered it advisable to ascertain the effect of the presence of copper on the estimation of sulphur by the new process. Twenty-five pounds of grey pig-iron smelted from Spanish ores were melted with two ounces of commercial copper; the resulting metal proved, on analysis, to contain 0.43 per cent of copper. The sulphur yielded by the aqua regia process amounted to 0.017 per cent; that obtained by the new method was 0.02 per cent. Thus, the presence of copper does not impair the accuracy of the results. Under the conditions of the analysis the solution was found to be free from any trace of copper, and the whole of the latter was found to be precipitated in the metallic form along with the graphite and silica.

In conclusion, the authors commend this process to the notice of steel analysts, feeling sure that a method so rapidly carried out and so accurate in the results it yields will be gladly accepted in the place of an operation so tedious and disagreeable as the estimation of sulphur by the aqua regia and barium sulphate method.

POISONS AND POISONING.

By C. MEYMOTT TIDY, M.B., M.S., &c.,
Professor of Chemistry and of Forensic Medicine at the London
Hospital, &c.

(Concluded from p. 35).

THERE naturally follows on what I have said respecting this chemical action of poisons, the following important question:—

Given knowledge of certain properties of the elements, such as their atomic weights, their relative position, according to the periodic law, their spectroscopic characters, &c.;—or given knowledge of the chemical composition, the molecular constitution, together with the general chemical and physical properties of compounds; in other words, given such knowledge of the element or compound as may be learnt in a laboratory—does such knowledge afford any clue whereby we may predicate the probable action of the element or of the compound respectively, on the living body?

First let us limit our attention to the *elements*.

The starting-point of this inquiry was the toxic properties of the metals. The work of Blake (1841) in this

direction was afterwards extended by Rabuteau (1867). Their observations led them to the general conclusion that "the physiological activity of the metals increased with their atomic weight." This broad general statement was modified at a later period by noting that the reverse was the case with certain groups of metals. Thus potassium (39) is more poisonous than sodium (23), and barium (137) more poisonous than calcium (41). These facts led Rabuteau to the conclusion that any comparisons of toxicity must be limited to the metals belonging to the same group. Husemann and Richet, however, pointed out that even this rule did not hold good, seeing that lithium having an atomic weight of 7, was far more poisonous than either sodium or potassium.

Experiments on the metals were further conducted by Richet with the metallic chlorides. Grain by grain, at intervals of forty-eight hours, he added the chlorides to water in which he kept fish of a given kind. He then recorded the maximum strength of the solution of the metallic chloride in which these said fish would live for forty-eight hours. The conclusion at which he arrived was that the limits of the toxicity of a metal bore no relationship either to its atomic weight or to any other chemical or physical characteristic of the metal.

Bouchardat and Stewart Cooper in a similar manner experimented with the non-metals. Selecting the haloid group of elements, they noted that their toxicity was inversely to their atomic weight, fluorine (19) being the most poisonous, and iodine (127) the least poisonous of the group, chlorine (35.5) and bromine (80) occupying their proper intermediate positions. But here again the group theory was inevitable. What was true of monad elements was not true of the elements of higher atomicity, the toxicity of selenium (79) being far greater than that of sulphur (32).

With these facts before us there arises this question, Was a relationship to be expected between physiological action and atomic weight? One poison acts on muscles—a second on nerves and nerve-centres—a third on the blood:—Is it likely, even supposing a relationship to exist between a certain group of elements and a given organ or a given structure, that the relationship would be the same in the case of all organs and all structures? These researches (the outline of which I have briefly indicated) suggest this much to future observers, viz.: First of all group your poisons according to their methods of operation, and then see how far the degree of toxicity of the terms of any one group show relationship to the atomic weights of such group.

But the difficulties of comparison thicken, when we consider the physiological action of certain allotropic modifications of the elements.

Thus compare *yellow* phosphorus, a body readily inflammable, soluble in bisulphide of carbon, firing by contact with iodine, with *red* phosphorus, a body at variance with the yellow variety in the three respects named. Nor is this all. For *yellow* phosphorus is an active poison, two grains being a certainly toxic dose, whilst *red* phosphorus is an absolutely inert body.

Take a second illustration. In its ordinary form oxygen plays the part of a life sustainer. But oxygen is only a life sustainer in its common form and at ordinary pressure.

On this latter point I have no time to dwell, save to mention that if an animal be exposed to oxygen at three pressures, the resulting symptoms are not unlike those induced by strychnine.

There is, however, an allotropic form of oxygen called *ozone*. The physiological action of ozone was the subject of a communication to the Royal Society of Edinburgh by Dewar and McKendrick (1873). Their experiments were made on both cold- and warm-blooded animals, including amongst the latter themselves and their assistants.

The results are remarkable, more particularly when we remember that the air with which they operated at most only contained 10 per cent of ozone.

* A Lecture delivered before the Royal Institution of Great Britain, March 2, 1888.

Placing a large frog in a jar of air, and then ozonising the air, the frog in about half a minute closed its eyes, the respirations fell from 96 to 8 per minute, and the body temperature was lowered 4° or 5° C. The animal recovered in about 8 minutes, when pure air was admitted into the receiver. Death resulted if the animal was exposed for any lengthened period to the action of the ozonised air.

As regards the action of ozone on warm-blooded animals, Dewar records certain personal experiences, chief amongst which were a tendency to breathe slowly, an enfeebled pulse, and fits of sneezing.

But now comes the curious part of the story, viz., that at the *post-mortem* on the animals that died under the influence of ozone, the blood was found to be *venous*. (The results were similar when pure ozonised oxygen was employed). It is most remarkable that the *post-mortem* appearances of death from an intensified oxygen should resemble those of death from carbonic acid.

I give these illustrations to show why there should be reason to doubt whether the physical or chemical properties of an element can ever suggest either toxic activity or physiological action.

2nd. Compounds.

Is there any relationship between the chemical composition or constitution of a compound body and its physiological action?

The first series of researches on this question was directed to determining whether, in the case of a salt, the acid or the base was, physiologically, the most important ingredient (Blake, 1841).

No doubt most often the active agent of a salt is the base, but this is by no means uniformly the case. Probably the solubility of a compound and the different proportions of acid to base in the salt (*i.e.*, whether the compound in question be an acid or a basic salt) are agencies which also help to determine the toxicity of the body and its physiological action.

A second series of experiments was made by Blake for the purpose of showing that, given a series of isomorphic salts, the intensity of physiological action increased with the molecular weight. He further contended that salts crystallising in different forms had different physiological actions. On this basis he constructed a series of nine groups of salts, each group being characterised by special physiological actions, insisting with much reason that we possess in living matter a reagent (so to speak) capable of aiding us in our investigations into the molecular properties of chemical compounds. If from molecular constitution you can determine physiological action, probably from physiological action, conversely, you may determine molecular constitution.

Another series of experiments in a similar direction were made by Schoff on the Continent, and by Fraser and Crum Brown in this country.

Of these experiments the most important are those indicating how, from bodies of vastly different physiological action, you may obtain derivatives having similar properties.

For example, the physiological action of *strychnine* is primarily exerted on the spinal cord. As a result, convulsions occur as a prominent symptom. But if we introduce into the strychnine molecule a methyl group (forming methyl-strychnine), the action of the drug is altered—methyl-strychnine paralysing (strychnine stimulating) the motor nerves.

But here comes a curious fact. If we take morphine, or nicotine, or atropine, or quinine, or veratrine (none of which bodies are comparable in their physiological action to strychnine), and convert them into their methyl derivatives, the methyl compounds formed (*viz.*, methyl-morphine, methyl-nicotine, &c.) are comparable in their physiological action to methyl-strychnine.

We must admit these experiments to be striking. One treasures any experiment suggestive of the chemical constitution of a body indicating physiological action.

But again:—The true physiological action of a drug is not so much its general as its selective action, this selective action being largely dependent on the *dose* administered and the mode of administration.

For example:—Inject into the circulation of a frog a *small* dose of *veratrine*, great muscular stiffness results, a *large* dose similarly administered not producing this effect. And now change the method of administration: Apply the *small* dose directly to the muscle, you get no symptom; but apply the *large* dose directly, and great muscular stiffness results. Here see the modifying influence of dose and of the mode of administration.

Again, the difficulty of "allotropism" in the case of elements finds its counterpart in "isomerism" in the case of compounds. Thus, cyanogen and para-cyanogen are bodies of identical *percentage* composition, and yet cyanogen is one of the most poisonous of gases, whilst para-cyanogen is one of the most inert of solids.

Or, again, take *piperin* and *morphine*. These bodies are of identical percentage and molecular composition. They agree (it is true) in being poisons. But how vastly different their physiological action!—the one an extreme irritant, the other a powerful narcotic.

I fear we must admit that, as no *à priori* reasoning could predict that by combining copper and sulphuric acid a blue salt would be formed, so no *à priori* reasoning, no knowledge of chemical constitution, can predicate what will be the special organ on which any given poison will act, nor, even supposing that the organ upon which the chemical activity of the drug will be exerted be known, what will be the nature of such chemical action. The science of drugs, like the science of chemistry, is, and must ever remain, an experimental science.

And, be it remembered, the poisons of the toxicologist are the medicines of the physician. Physiological action is a subject-matter for experiment. Let the guard be jealously set and as rigidly maintained to prevent cruelty to animals; but ask yourselves, whether to rob the higher creation of life and health rather than that one of the lower creation should suffer, be not a refinement of cruelty—the cruelty of cruelties? "Are ye not of much greater value than they?" speaks a still small voice amidst the noisy babble of well-intentioned enthusiasts.

Two general observations are suggested. And this first:—The later age history of poisoning is the history of a profession. This profession we find closely associated, not only with the profession of medicine (the art of healing), but with witchcraft, incantation, and charms. The threefold arts of poisoning, witchcraft, and medicine, moreover, became so closely allied to religion as to claim, each and all, the shield of a sacred sanction and the protection of a divine voice. Even that very word *φάρμακός*, the Greek for "a dispenser of medicines," is the same word used to imply "a witch" and "a poisoner." The modern scientist has once and for ever shattered the bond that united science with superstition. It was a special ministry of science to teach men that in the preparation of medicines the pharmacist required no stuffed crocodile to preside over the mysteries of his laboratory, nor incantation to give virtue to his drugs!

And this secondly: the villainies of the early poisoners can never again be practised in the light of the science of the nineteenth century. Science can and has done what legislation could never do. The Hebrew Scriptures speak of a time when "the sucking child shall play on the hole of the asp, and the weaned child shall put his hand on the basilisk's den" (Is. xi., 8, Rev. Ver.). Is not science working out some such consummation as this? I claim that a science which, like a blood-hound, can track with cunning scent the minutest atom of a poison in the body, is helping forward the day when poison shall cease to be the instrument of a secret treachery, because there are eyes it cannot hope to evade, and a science whose investigations it will not dare to defy.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING JUNE 30TH, 1888.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolis Water Act, 1871.

London, July 7th, 1888.

SIR,—We submit herewith the results of our analyses of the 182 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from June 1st to June 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

During the past month a considerable proportion of the daily samples, drawn from the East London Company's mains, have been found, when examined by transmitted light, to be slightly turbid, from the presence of finely diffused, suspended mineral matter, attributable to the considerable disturbance of the Company's mains by the provision now being made of a number of new hydrants.

With this exception the character of the entire supply of water to the Metropolis by the seven Companies, dependent on the Thames and the Lea, has been thoroughly satisfactory.

Attention has been called from time to time to the, for the most part, minute seasonal differences in the composition of filtered river-water as it is supplied to London. Such a difference is noticeable when comparison is made of the mean results of the examinations conducted during the past month of June, with the closely agreeing mean results of the examinations made in the previous months of April and May. Thus the mean numbers expressing the organic carbon, the oxygen absorbed, and the degree of colour-tint of the Thames-derived water supplied during the months of April and May, being 0.157, 0.046, and 16.2 respectively, the corresponding numbers for the month of June were found to be 0.147, 0.038, and 11.6 respectively.

Moreover, the maximum amount of organic carbon in any one sample examined in April and May being 0.183 part in 100,000 parts of the water, the maximum amount found in any one sample examined during last month was only 0.157 part,—a proportion but little removed from the mean or 0.147 part in 100,000 parts of the water.

During the past quarter of the year we have examined 532 samples of the water furnished by the seven London Companies taking their supplies from the Thames and the Lea. Notice has been taken of the recent deficiency in clearness of many samples of the East London Company's water. Throughout the quarter, however, the whole of the samples taken from the other six Companies' supplies of water were found to be well filtered, clear, and bright.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.
WILLIAM ODLING.
C. MEYMOTT TIDY.

NOTICES OF BOOKS.

Alkali, &c., Works Regulation Act, 1881. Twenty-fourth Annual Report on Alkali, &c., Works by the Chief Inspector. Proceedings during the year 1887 presented to the Local Government Board and to the Secretary for Scotland. London: Eyre and Spottiswoode.

THE first point here to be noted is the number of chemical works registered under the Act. These amount now to 927 in England and Ireland, being an increase of 17 as compared with the total in 1886. In Scotland the registered works amount to 139, making the grand total for the United Kingdom 1066. But though the entire number of chemical works has thus increased that of alkali works, strictly speaking, has progressively decreased during the past three years. In 1885 there were in operation 132, in 1886 118, and in 1887 only 116. It is noted that the works themselves have been very generally enlarged, and that in most of them several processes are being carried on. The total number of alkali works is given as 66; places where hydrochloric acid is made by the cylinder process, 28; copper works using the wet process, 21; carbonising cotton, 7; sulphuric acid works, 324; chemical manures, 242; gas-liquor works, 26; nitric acid, 96; manufactories of sulphate and muriate of ammonia, 311; chlorine and bleaching-powders, 58; salt, 78; and cement, 94.

During the year 4383 visits have been made and 4402 tests applied. We are glad to find that the principles of Dr. Angus Smith are still being carried out. If the inspectors find some works in an unsatisfactory condition they make repeated visits, not with a view to obtain evidence for a prosecution, but to effect the needed improvement,—to trace out the source of the difficulty and assist in finding means for its removal. The Report informs us that "such action on the part of the inspector, though not always welcome at the time, is ultimately acknowledged with satisfaction by the manufacturer, and the expense that may have been incurred is felt in the end to be money well spent."

Obviously such a policy on the part of the inspectors demands not alone a sound practical insight into the physics and chemistry of the question, but it requires courtesy, firmness, and tact. But we shall not be accused of flattering Mr. Fletcher and his assistants if we say that in their hands the Act is being worked admirably—that is, with the greatest possible protection to the public against injury and nuisance, and at the same time with the minimum of inconvenience to the manufacturer. The following figures will show that we are not painting the result too much in rose-colour. The hydrochloric acid in the chimney-gases, calculated as grains per cubic foot, has been for the last three years stationary at 0.10. The proportion of hydrochloric acid escaping as compared with that generated, which was 2.39 per cent in 1885 and 2.13 in 1886, was in 1887 only 1.99. The acid gases escaping from the chambers given as grains of sulphuric anhydride per cubic foot, is nearly stationary. In 1885 it was 1.52, in 1886 1.40, and last year 1.50. The total acidity of chimneys given as SO₃ varies little, the amounts for the last three years being respectively 0.67, 0.77, and 0.74. In the acidity of gases from manure works there has been a steady improvement from 0.67 grain in 1885 to 0.44 in 1887.

All these figures are well within the limits fixed in the Act. The escape of hydrochloric acid has been 1.10th grain for each cubic foot of chimney smoke. The Act allows double the quantity. The proportion of the same acid gas which may lawfully escape is 5 per cent of the total generated. In practice it is now less than 2 per cent. The limit enacted for the escape of chamber gases is 4 grains of sulphuric anhydride per cubic foot, whilst the average actual escape is now 1½ grains.

Only four prosecutions under the Act took place during

the year. Three of them were for neglecting to register works which came within the scope of the Act, and one, a manure works was for not using the best known means for preventing nuisance.

A very important point mentioned in this Report is the struggle between the Leblanc and the Solvay alkali processes. About £3,000,000 are supposed to be invested in the Leblanc process, and most of this would be wasted if the Solvay process is successful. The question seems to turn mainly on the by-products. If the Solvay makers can utilise their chlorine, so as to produce bleaching-powder and chlorate of potash as cheaply as their rivals, the Leblanc works must be closed. If, on the other hand, the Leblanc makers can recover more available chlorine from the salt decomposed, and if they can further recover the sulphur now thrown away in the form of vat-waste, their future is secured. It is here mentioned that Messrs. Chance, of Oldbury, recover very nearly the whole of the 15 per cent of sulphur present in this waste. The quantities of vat-waste existing and still produced are fearful. Deposits of it at Widnes cover 450 acres and contain about 8,000,000 tons, to which there is made a daily addition of 1000 tons. The total yearly production is no less than 1½ million tons.

The total weight of salt decomposed in the alkali manufacture was, in 1887, 736,017 tons, of which 577,381 tons were used in the Leblanc process.

Hopes are expressed that either by means of Mr. Hargreave's thermomotor, or Mr. Mond's system of producing fuel gas, the production of black smoke may come to an end.

Not the least useful part of the Report is that where the Inspector points out the omissions and anomalies of the Act as it stands. Thus, a variety of processes in which sulphuretted hydrogen is given off are under no control. The production of sulphurous acid for any purpose save the manufacture of sulphuric acid does not fall within the cognisance of the inspectors. Though the manufacture of nitric, sulphuric, and hydrochloric acids is strictly regulated, yet their use is not noticed, however great the quantities of acid fumes given off. The use of nitric acid, *e.g.*, does not come within reach of the Act unless some process is adopted for condensing the fumes. "This is generally accomplished by a process of oxidation in which nitric acid is re-formed. As this, in a sense, is a manufacture of nitric acid, the operation comes under the Act and the works are inspected, and in an extreme case, if the condensation and retention of the acid were negligently and imperfectly performed the manufacturer might be fined. But should a neighbouring manufacturer make no attempt at condensation, but allow the whole of his nitrous fumes to escape unchecked, he would do so with impunity as far as the Alkali Act is concerned."

It would be well if the Act could be extended so as to embrace all offensive gases or vapours, from whatever business arising, and if the measure could be not "cumulative" but codifying, so as to embrace the entire law as regards volatile or air-born nuisances.

has raised pure physics to what it is, we may expect that chemical phenomena may be rationally dealt with, and explained with great advantage.

Why is it that we cannot generalise on known chemical facts so as to predict a result without the chance issue of experiment?

I have often heard it said that chemistry and mathematics do not blend well in the scientific mind. Mathematicians have certainly not given that assistance to chemistry which might have been expected, and this can only be explained by assuming that rigidly mathematical methods are beyond the grasp even of an intelligent and well-informed average chemist.

A fair knowledge of the differential calculus and trigonometry, so far as being able to deal with the transformations of angular functions, is a very powerful help to the chemical physicist.

Mathematicians make the mistake of writing exclusively for a well-trained mathematical mind, with the result that chemists will not, as a rule, trouble themselves to examine the methods or deductions.

Chemists can only recognise realities and can only accept probabilities so far as they are consistent with experimental deduction; these are advantages of primary importance, and which, I am sure, will not be surrendered. Accurate and careful observations are the very first requirements in a conscientious chemist.

There are certain chemical changes which we know are produced by heat, electricity, &c., and which purely chemical methods cannot detect; these changes are revealed to us by the thermometer, expansion, galvanometer, electrolysis, &c.

The elements arsenic, antimony, and bismuth stand, as it were, on the border-land of metals and non-metals. Arsenic alloyed with copper reduces the electrical conductivity of the latter as no true metal does; it behaves more like a non-metal, as sulphur, oxygen, phosphorus, &c. Then follows antimony and bismuth. The non-metals have a very high resistance, but the resistance of a copper wire containing a little oxygen or sulphur cannot be expressed by the average resistance, but if we assume that the copper compounds are formed and exist as masses, offering an impediment, *en bloc*, to conduction, and intermingled with the remaining copper, the phenomenon is intelligible.

Dissociation of a compound or alloy at high temperatures we know does take place. It is quite possible to determine the energy required to break up, say, a compound molecule, and to express the same in terms of the mechanical unit. It is no less easy to determine what compounds are possible to exist at certain temperatures. Chemistry alone will not help us here, but still these considerations come fairly within its domain; the sooner we recognise this fact the better. There is an idea that chemistry and physics must be severed. I am sorry to record this, especially when we bear in mind the recent chemical applications resulting from electrolysis.—I am &c.,

THOMAS T. P. BRUCE WARREN.

CORRESPONDENCE.

THE MATHEMATICAL INVESTIGATION OF CHEMICAL PHENOMENA.

To the Editor of the Chemical News.

SIR,—Whilst recently examining the subject of molecular stability I have been convinced of the value of mathematical reasoning to chemical science. We can often apply mathematical analysis to explain the probable nature of a chemical change where chemistry itself would help us very little. I feel confident that as mathematics

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 2, July 9, 1888.

Researches on Hexagonal Phosphorescent Blende.—A. Verneuil.—The würtzite obtained artificially is very phosphorescent if we cause a desulphurising agent to act upon the original blende. The phosphorescence of this

product, formed in a neutral atmosphere, is the more lively the lower the temperature at which it is produced.

Certain Compounds of Yttrium.—A. Dubois.—The author has prepared certain compounds of yttrium by the dry way. Among those obtained are a silicate, $Y_2O_3 \cdot SiO_2$, analogous to neutral gadolinite, and a crystalline yttrium oxide.

Syntheses by Means of Cyanacetic Ether.—Alb. Haller.—The author has obtained the ortho-toluylic, phenacetylic, cinnamyl, and di-cinnamyl-cyanacetic ethers by the process which he formerly used and described for the preparation of the benzoyletic, acetylic, propionyletic, &c., ethers. The author purposes studying the action of ammonia, aniline, &c., upon all these cyanic ethers.

On Pelimelic Acid derived from Menthol.—G. Arth.—A critique of the researches of Herr Mehrländer. M. Arth thinks that the constitution of the acid, $C_7H_{12}O_4$, is not yet established, and the series of oxidation products of menthol imagined by Herr Mehrländer is still hypothetical.

The Alkaloids of Cod-liver Oil.—Arm. Gautier and L. Mourgues.—The fraction boiling from 87° to 90° contains butylamine; that from 96° to 98° , amylamine; a little above 100° , hexylamine; that boiling 198° to 200° , hydro-lutidine, a new base; part of the fixed bases giving a hydrochlorate immediately precipitable in the cold, asselline, a new base; portion of the fixed bases yielding a very soluble chloroplatinate which crystallises from the mother-liquors of the former, morrhaine, a new base. There exists also in cod-liver oil a little lecithine and a very peculiar crystalline nitrogenous acid, *gaduinic acid*. It is at once a powerful acid and an alkaloid capable of forming crystalline chloroplatinates.

The Production of Propylene Iodide by the Fixation of Hydriodic Acid upon Allyl Iodide. Trans-formation of Propylene Iodide.—H. Malbot.—Simpson announced that allyl iodide was directly convertible into isopropyl iodide by a current of hydriodic acid. Erlenmeyer admits the formation of propylene as an intermediate product. The author finds that a large quantity of propylene iodide is produced, and, according to circumstances, is transformed into isopropyl iodide, without escape of propylene, or is split up into propylene and iodine without formation of isopropyl iodide.

Action of Ammonia upon Epichlorhydrine.—Ad. Fauconnier.—The author obtains, by a process which he describes in full, trichlor-oxy-propylamine, a very unstable base, $(C_3H_6ClO)_3N \cdot HCl$.

The Peptonic Fermentation of Meat.—V. Marciano.—If chopped meat is mixed with the juice and the pressed tissues of the agave the fibrine is dissolved in five or six hours with a yield of 20 per cent of peptone, which is almost theoretical.

—
Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 1.

Analysis of Nickel Silver.—Dr. Felix Oettel.—The solution obtained by dissolving the metal in nitric acid, and thus, if needful, freed from tin, is evaporated with sulphuric acid (using to $\frac{1}{2}$ grm. metal 15 or 20 drops of the mono-hydrated acid), and thus separating out the lead as sulphate. To the liquid thus freed from lead and tin, and amounting to about 100 c.c., there are added 2 c.c. of strong hydrochloric acid and sulphuretted hydrogen is passed in. When the precipitation is complete, which is known by the rapid subsidence of the copper sulphide, it is heated for a few minutes to a boil, cooled again, a few bubbles of sulphuretted hydrogen are passed in (which occasion no turbidity if the precipitation was complete), and filtered. The copper sulphide thus obtained, which is rather dense and does not readily oxidise

in the air, is washed on the filter, first with very dilute hydrochloric acid containing sulphuretted hydrogen, and then with water (to which a little sulphuretted hydrogen-water has been added) until the acid reaction disappears. When dry it is weighed as a sulphide in a Rose crucible. It is necessary to add a little sulphur before heating only if the quantity is very trifling. As soon as the odour of sulphurous acid has disappeared it is still ignited for three minutes in a slow current of hydrogen, and is then allowed to cool in the same current. When thus obtained the copper sulphide has at once the correct weight. When the copper has been removed the zinc is separated according to the method of Smith and Brunner, by passing sulphuretted hydrogen into a perfectly neutral solution. After some time a few drops of sodium acetate should be added to neutralise the acid liberated and prevent imperfect precipitation. The author, however, prefers to add the sodium acetate at once after neutralising and before introducing the sulphuretted hydrogen. White pulverulent zinc sulphide is then deposited, which, after standing for a few hours, may be filtered and washed with sulphuretted hydrogen water without running through the filter turbid. The precipitate, when dry, is ignited in a Rose crucible in a current of hydrogen, and weighed as zinc sulphide. The solution still contains nickel, cobalt, iron, and generally a little manganese. The filtrate is boiled to expel sulphuretted hydrogen, oxidised with bromine water, the iron precipitated with ammonia as a basic salt, purified by re-precipitation, the mixed filtrates are rendered strongly ammoniacal and submitted to electrolysis. Nickel and cobalt separate upon the platinum cone as a firmly adhesive layer. When the precipitation is complete the cone is lifted out, rinsed with the washing bottle, plunged in ordinary alcohol, and dried over a small gas-flame. Any manganese present is separated out during the electrolysis in brown flakes; it is filtered off and weighed as manganous-manganic oxide.

Determination of Alumina in Presence of Ferric Oxide and Phosphoric Acid.—L. Blum.—This paper will be inserted in full.

Detection of Sodium Phosphate in Vitreous Phosphoric Acid.—Anton Battendorff.—This impurity may be detected by dissolving the sample in strong hydrochloric acid. Sodium chloride remains on account of its sparing solubility in strong hydrochloric acid.

Method for Generating Pure Non-arseniferous Sulphuretted Hydrogen.—Clemens Winckler.—The author takes 100 parts heavy spar, 25 parts of coal-dust, and 20 parts of common salt. The two former ingredients are finely ground, the salt is added, and the whole made up with a little water into a ball, which is rammed into a crucible of 25 c.m. in height and 10 c.m. in width. When dry some coarse coal is laid above the mass, the lid is put on, luted down, except a small vent-hole, and heated for some hours to incipient whiteness. The heat is then let go down, the crucible taken out of the furnace, and let cool quickly. The barium sulphide must be preserved in stoppered bottles in a dry place. With dilute hydrochloric acid it yields a very regular current of sulphuretted hydrogen, free from arsenic.

New Apparatus for the Direct Determination of Carbonic Acid.—O. Ostersetzter.—This paper cannot be reproduced without the accompanying cut.

Apparatus for the Extraction of Fats.—O. Foerster.—This paper requires the accompanying illustration.

Examination of Powdered Spices.—Eugene Borgmann.—As a preparation for examination with the lens the author stirs up 1 grm. of the powder with 10 c.c. of water and pours the whole rapidly upon a slab of unglazed porcelain. As the water is absorbed the powder is left upon the plate finely distributed, so as to be ready for examination.

The Use of Asbestos in Filtration.—W. Fresenius.—Liquids containing very finely divided matter in sus-

pension may be brought to settle by shaking them up with asbestos.

Determination of Arsenic in Pyrites.—H. Fresenius.—The fusion method offers no advantages in comparison with the direct distillation with ferrous chloride of a solution obtained by heating in a current of chlorine or by treatment with hydrochloric acid and potassium chlorate.

Indicators for Alkalimetry and Acidimetry.—A number of substances proposed in the *Analyst*, *CHEMICAL NEWS*, *Pharmaceutical Journal*, *Comptes Rendus*, *Journal of the Society of Chemical Industry*, and *Chemiker Zeitung*. It is remarked by E. Dietrich that blue litmus-paper becomes more sensitive if kept for some months, whilst the sensitiveness of red litmus and turmeric papers is unchanged.

Separation of Alumina and Glucina.—A. Zimmermann.—The author has examined the methods hitherto proposed, and finds the results partly uncertain and partly quite useless. The best method is the use of pure potassium hydroxide, in which, if in excess, glucina dissolves in the cold and is again deposited on boiling. A volume of 300 c.c. solution, containing 0.3 gm. of substance, allows of a perfect separation. If the liquid is much diluted, alumina falls along with glucina. Caustic soda is not applicable.

Determination of Small Quantities of Bismuth and Antimony in Commercial Copper.—P. Jungfer.—The author dissolves the copper in nitric acid, dilutes slightly, adds sodium carbonate drop by drop, stirring well, until a slight permanent precipitate has been produced, stirs further for a few minutes, and lets stand for an hour or two in order that any bismuth remaining in solution may have time to undergo double decomposition with the basic copper carbonate deposited. The precipitate is filtered through a small filter, dissolved in a few drops of hydrochloric acid, and diluted with water. The bismuth is then deposited as basic bismuth chloride, which is collected upon a tared filter, dried at 110° and weighed. If a residue appears on dissolving the copper it is filtered off, melted with sodium carbonate and sulphur, and examined for bismuth. For separating small quantities of arsenic and antimony from copper Flajolot proposed a method based on the different behaviour of the iodides of the above elements. The copper iodide is almost insoluble in feebly acid solutions in which arsenic and antimony iodides (the latter in presence of tartaric acid) are readily soluble. P. Jungfer has re-examined this method, and finds that along with copper arsenic remains entirely in solution, and that antimony, even in presence of tartaric acid, is partially carried down, and can be removed only by very protracted washing. This objection the author gets over by adding to the solution a little potassium fluoride before the potassium iodide; in this manner the copper iodide can be freed from antimony by a short washing, even if the addition of tartaric acid is omitted. For determining small quantities of antimony in copper the author dissolves 10 grms. copper in 50 c.c. nitric acid of specific gravity 1.4, dilutes the solution in a large beaker to 200 to 300 c.c., and after adding 150 mg. of dissolved potassium fluoride, mixes with potassium iodide and sulphurous acid. The precipitation of the copper iodide is effected in the cold by adding the requisite potassium iodide, not at once but in successive portions alternately with sulphurous acid, avoiding an excess of the iodide. The beaker is set on a boiling water-bath until the precipitate has deposited, the contents are then filtered, and the precipitate is washed by decantation three or four times with hot water containing sulphuric acid. After the excess of sulphurous acid in the filtrate has been removed by means of solution of iodine, sulphuretted hydrogen is introduced for a long time. The precipitate produced contains, along with arsenic and antimony, a little copper and any lead and bismuth which may be present. The sulphides are filtered off and dissolved in hydrochloric acid with a little potassium chlorate.

From the liquid thus obtained, after adding tartaric acid and excess of ammonia, copper, lead, and bismuth may be removed by the cautious addition of sulphuretted hydrogen water. After the precipitate has been gently heated and stirred for a short time it is rapidly filtered, and arsenic and antimony in the filtrate are separated from each other in the ordinary manner.

Quantitative Determination of Gold and its Separation from the Platinum Metals.—L. Hoffmann and G. Krüss.—Noticed already under *Liebig's Annalen*. It is remarked in the work of R. Fresenius on "Quantitative Analysis," 6th Edit., vol. i., p. 623, that gold can be separated from all the oxides of the groups I. to V. by means of oxalic acid with the exception of lead oxide, mercurous oxide, and silver oxide in hydrochloric solution. Hoffmann and Krüss remark that soluble mercurous salts cannot exist in presence of auric chloride, as they become converted into mercuric compounds, and reduce the gold to aurous oxide. If, therefore, gold and mercury exist simultaneously in a solution, both must be in the higher state of oxidation, and in this case oxalic acid is the only good agent for their separation.

On Sulphurous Acid and Iodometry.—J. Volhard.—Sulphurous acid is decomposed by hydrogen iodide with formation of iodine, water, and sulphur (a little hydrogen sulphide). Sulphurous acid in a saturated aqueous solution is decomposed by hydrogen iodide. The iodine is here not set free, but re-converted into hydrogen iodide with formation of sulphuric acid. Thus, the total result of the reaction is a catalysis of sulphurous acid into sulphur and sulphuric acid. This reductive action of hydrogen iodide is avoided if a moderately strong solution of sulphurous acid is poured into the solution of iodine. With this modification Bunsen's iodometric method is the most accurate known.

A Peculiar Reaction of Malonic Acid.—S. Kleemann.—Malonic acid dissolves readily in acetic anhydride in the cold. If the solution is heated carbonic acid is evolved, the liquid turns yellow and then reddish yellow, with a very strong yellowish green fluorescence like fluoresceine.

Detection of Furfural.—H. Schiff.—The author adds a mixture of equal volumes of xylydine and glacial acetic acid mixed, containing also a little alcohol. This reagent gives an intense red colour, even with minute traces of furfural.

Kjeldahl's Determination of Nitrogen.—Karl Ulsch.—The author had formerly recommended an addition of copper oxide and platinum chloride during the action of the sulphuric acid. He now gives a caution against the use of an excess of platinum chloride and against prolonged heating.

Volumetric Determination of Phenyl-hydrazine.—E. von Meyer.—From the *Journal für Prakt. Chemie*.

Influence of Inactive Bodies upon the Rotatory Power of the Solutions of Tartaric Acid.—D. Gernez.—Noticed under *Comptes Rendus*.

Determination of Acetic Acid in Liquids containing Organic Matter.—H. W. Wiley.—From the *American Chemical Journal*.

Examination of Water.—According to Meade Bolton the number of bacteria in a sample of water shows neither its chemical nature, nor its degree of pollution, nor the danger of infection. Heräus and Flügge recommend that samples of water should be put in glass tubes, previously sterilised, sealed before the blowpipe, and packed in ice.

Milk.—Matthew A. Adams.—From the *Analyst*. Methods indicated by other chemists are given, taken from the *CHEMICAL NEWS*, *Analyst*, *Journal of the Chemical Society*, *Chemiker Zeitung*, *Comptes Rendus*, &c. According to the *Pharmaceut. Zeitung*, H. Thoms has detected ultramarine in a sample of trade-milk.

NOTES AND QUERIES.

**** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.**

Glutina.—Will you kindly inform me through your paper what you think would be the best and cheapest things to mix with glutina, and to form a solid substance so that it will not (when hard) be brittle and break off short like lime, but will retain its starchy substance and adhesiveness, and form or press somewhat like *papier maché*?—**SPERO.**

FOR SALE.—THE CHEMICAL GAZETTE.

Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," CHEMICAL NEWS Office, Boy Court, Ludgate Hill London, E.C.

Silicates of Soda and Potash in the state of Soluble Glass, or in CONCENTRATED SOLUTION of first quality, suited for the Manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Soap Works, Widnes, Lancashire.

London Agents, **COSTE and Co.**, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

**ALLIANCE AND DUBLIN CONSUMERS' GAS COMPANY,
D'OLIER STREET, DUBLIN.**

The Directors of the above Company are prepared to receive Tenders for the purchase of Spent Oxide of Iron, produced on the Company's Works, the quantity being about 900 tons per annum. The Contract is to be for three or five years.

Specifications, giving particulars of sale and the nature of the proposed contract, can be had on application to the undersigned, at the Company's Offices, D'Olier Street.

Tenders to be lodged at the Company's Offices, D'Olier Street, on or before the 21st August, 1888, endorsed Tenders for Spent Oxide of Iron.

W. F. COTTON.
Secretary and Manager.

Offices, D'Olier Street, Dublin.
July 18th, 1888.

**UNIVERSITY COLLEGE, BRISTOL.
CHEMICAL DEPARTMENT.**

PROFESSOR—**SYDNEY YOUNG, D.Sc.**
LECTURER—**ARTHUR RICHARDSON, Ph.D.**

The SESSION 1888-9 begins on 10th October. Lectures on Inorganic, Organic, Advanced, and Photographic Chemistry will be delivered during the Session. The Laboratories are fitted with the most recent improvements for the study of Practical Chemistry in all its branches. In the evening Lectures on Inorganic Chemistry and on Photographic Chemistry at reduced fees are delivered. There will also be Courses of Lectures on the Chemistry of Potting and Brewing. Several SCHOLARSHIPS are tenable at the College. For Prospectus and further information, apply to the SECRETARY.

TESTS FOR SO-CALLED SACCHARINE, ANTIPYRINE, AND ANTIFEBRINE.

By DAVID LINDO.

Saccharine.

THE detection of this substance when mixed with other matters will seldom, I imagine, be possible unless it is first isolated in a state of at least tolerable purity. Chemical tests that can be easily applied for its identification in this condition are probably known and may have been published, but I have met with none, except production of salicylic acid from the compound by fusing it with potash or soda.

I have failed as yet to obtain a characteristic reaction for the substance in solution; the following test, which must be applied to the solid body, is believed to be original. It consists in evaporating to dryness on the water-bath, the saccharine mixed with excess of nitric acid; a fragment of caustic potash (not too small) is then added, and a drop or two of water, without removing the dish from the bath. Colour is at once developed, and if the dish is inclined streaks of colour, blue, violet, purple, and red, flow from the caustic; the reaction is very fine, and still more beautiful if 50 per cent alcohol is added to the potash instead of pure water. The test, however, is not extremely delicate; half a milligramme of saccharine in the solid state is about the smallest quantity that will give definite results. Heat is necessary to develop the colours, and apparently large excess of alkali. Soda does not appear to act as well as potash.

Colour reactions obtained with coal-tar products must always be suspected of not being characteristic; whether the one here described is peculiar to saccharine remains to be ascertained. Vitali's test for atropia is carried out in a somewhat similar manner, but requires an alcoholic solution of potash, and the colours are different.

Antipyrine.

Knorr, who appears to have discovered antipyrine gives reactions by which it can be identified.

1st. Even a highly dilute solution of the substance in water gives a red colour on addition of a drop of ferric chloride solution.

2nd. This depends on the formation of what Knorr, in 1884, called diquinizine blue. The solution of antipyrine is mixed with a dilute solution of nitrite and a few drops of dilute sulphuric acid added. If the quantity of antipyrine present is not too minute a blue colour is developed, otherwise the colour may be green.

Knorr (*Journal of the Chemical Society*, 1884, p. 1378), states that nitro-antipyrine is obtained by gently heating a solution of antipyrine in concentrated nitric acid, that it crystallises in white needles, is insoluble in water and alkalies, but is sparingly soluble in strong nitric and hydrochloric acids. It is scarcely likely he overlooked a fine colour reaction, which may be obtained by heating antipyrine with strong nitric acid in a small porcelain basin over the lamp until reaction commences; the lamp is then withdrawn, and when the reaction ceases a fine purple-coloured liquid residue remains. On adding water and filtering a beautiful purple-red filtrate is obtained, and a violet-coloured precipitate remains on the filter. The reaction is very delicate. I have seen no reference to it in the abstracts of Knorr's papers that have come under my notice, nor elsewhere

Antifebrine.

I have met with no published tests for this body, and the only one I have discovered as yet must be applied to the solid substance; a very minute quantity, however, will suffice. The test depends on the fact that when antifebrine is heated strongly with concentrated sulphuric acid sulphanilic acid is formed, or at least a body which reacts exactly like it with nitrous acid and phenols. A small quantity of antifebrine is placed in a porcelain basin, a little pure concentrated sulphuric acid added, and heat applied with a naked flame until the acid fumes strongly; when cold, add a little water and mix with very highly dilute solution of nitrite; the mixture can now be tested with α -naphthol, thymol, or carboic acid.

For further particulars I must refer to a former paper of mine, published in the *CHEMICAL NEWS*.

EFFECTS OF DIFFERENT POSITIVE METALS. &c., UPON THE CHANGES OF POTENTIAL OF VOLTAIC COUPLES.*

By Dr. G. GORE, F.R.S.

IN this research numerous measurements were made, and are given in a series of tables, of the effects upon the minimum point of change of potential of a voltaic couple in distilled water (*Roy. Soc. Proc.*, June 14, 1888), and upon the changes of electromotive force attending variation of strength of its exciting liquid (*Ibid.*) obtained by varying the kind of positive and of negative metal of the couple and by employing different galvanometers. The measurements were made by the method of balance through a galvanometer, with the aid of a suitable thermoelectric pile (*Proc. Birmingham Phil. Soc.*, vol. iv., p. 130; *Electrician*, 1884, vol. xi., p. 414). The kinds of galvanometer employed were an ordinary astatic one of 100 ohms resistance and a Thomson's reflecting one of 3040 ohms resistance.

The following were the proportions of hydrochloric acid (HCl) required to change the potential of different voltaic couples in water:—

TABLE I.—Hydrochloric Acid.

Astatic galvanometer.			
Zn+Pt ..	Between 1 in	9,300,000 and	9,388,185
Cd+Pt ..	" "	574,000	637,000
Mg+Pt ..	" "	516,616	574,000
Al+Pt ..	" "	12,109	15,000
Reflecting galvanometer.

Zn+Pt ..	" "	77,500,000	84,545,000
Cd+Pt ..	" "	3,470,112	3,875,000

* Abstract of a Paper read before the Royal Society, June 21, 1888.

The magnitudes of the minimum proportions of bromine required to change the potentials of the three couples in water varied directly as the atomic weights of the three positive metals.

With chlorine the following were the minimum proportions required:—

TABLE IV.—*Chlorine.*

With the reflecting galvanometer.

Mg+Pt Between 1 in 27,062,000,000 and 32,291,000,000

With the astatic galvanometer.

Mg+Pt	Between 1 in 17,000,000,000 and 17,612,000,000
Zn+Pt	" " 1,264,000,000 " 1,300,000,000
Zn+Au	" " 518,587,360 " 550,513,022
Cd+Pt	" " 8,733,585 " 9,270,833
Zn+Cd	" " 55,436 " 76,467

In the case of chlorine as well as that of bromine the magnitudes of the minimum proportions of substance required to change the potential of magnesium-platinum, zinc-platinum, and cadmium-platinum varied directly as the atomic weights of the positive metals.

The examples contained in the paper show that the proportion of the same exciting liquid necessary to disturb the potential of a voltaic couple in water varied with each different positive or negative metal, and that the more positive or more easily corroded the positive metal, or the more negative and less easily corroded the negative one, the smaller usually was the minimum proportion of dissolved substance necessary to change the potential.

By plotting the results in all cases it was found that the order of change of potential caused by uniform change of strength of liquid varied with each positive metal.

The results also show that the degree of sensitiveness of the arrangement for detecting the minimum point of change of potential depends largely upon the kind of galvanometer employed.

As a more sensitive galvanometer enables us to detect a change of potential caused by a much smaller proportion of material, and as the proportion of substance capable of detection is smaller the greater the free chemical energy of each of the uniting bodies (*Roy. Soc. Proc.*, June 14, 1888), it is probable that the electro-motive really begins to change with the very smallest addition of the substance, and might be detected if our means of detection were sufficiently sensitive, or the free chemical energy of the uniting bodies was sufficiently strong.

ADDITIONAL NOTE ON THE RELATIVE VALUES OF THE ATOMIC WEIGHTS OF HYDROGEN AND OXYGEN.

By JOSIAH PARSONS COOKE and
THEODORE WILLIAM RICHARDS.

THE preceding paper on this subject (*CHEM. NEWS*, vol. lvi., pp. 7, 17, 30) was already in print, and a number of the extra copies had been distributed, when the writer received a letter from Lord Rayleigh stating that he had been engaged on a similar work, and had observed that the glass balloon used in Regnault's method of weighing gas volumes, when exhausted, was sensibly condensed by the pressure of the air. Obviously, if this were true, the tare of the balloon thus exhausted would be too large in consequence of the lessened buoyancy of the atmosphere, and hence the subsequently observed weight of gas when the balloon was filled would be too small. A shrinkage amounting to a single cubic centimetre would make a difference of about 1.29 m.grms., and Lord Rayleigh suggested that our results might have been influenced by a constant error arising from this source. As the same balloon represented in Fig. 1 of the preceding paper had been used in all our determinations, and was still in good

condition, there was no difficulty in determining the amount of shrinkage under exhaustion, and thus finding the correction which ought to be applied to the results on this account. The method we used was briefly as follows.

The balloon was first exhausted, and then completely filled with boiled distilled water at an observed temperature. The weight of this water having been taken, and the internal volume of the balloon thus determined, a small portion of the water—190 c.c.—was run out, and the volume estimated both by direct measurement and also by re-weighing the balloon. With these data we could readily calculate the volume of air left in the balloon for any given temperature, and the small amount of water lost by evaporation in the subsequent exhaustion produced no sensible effect on the result, as a knowledge of the volume within 5 c.c. was all that the present problem required, and the water did not lose in weight more than 2 grms. during the whole series of experiments.

The balloon was now thoroughly exhausted, allowed to stand, and again exhausted several times, until a vacuum gauge connected with it remained constant over-night, and indicated the calculated tension of aqueous vapour, which showed that all the air—dissolved or otherwise—had been practically removed.

A sufficient mass of water was left in the balloon to sink it under water, and thus immersed in a large vessel filled with distilled water (which had been boiled an allowed to cool); it was now suspended from the beam of the balance used throughout this investigation. No air bubbles formed on the glass, and care was taken to remove all entangled air from the connecting tubes. The weight soon became constant, and the tare could be accurately determined within a centigram. The connecting tubes of the balloon were next lifted above the surface of the water, and, after carefully drying the inlet, the outside air was admitted, and the temperature of the water in the tank and the height of the barometer observed. On again immersing the balloon there was a large loss of weight—about 1.4 grms.—over six times the weight of air admitted—only about 0.2 grm. There had evidently been a marked shrinkage under exhaustion amounting to about 1.6 c.c. This decrease of weight was noted after the equilibrium had become constant, usually in about five minutes.

It is probable that the admitted air was saturated with moisture, and the calculation is based upon that assumption; but this would make no practical difference in the weight so far as the problem before us is concerned. Appended is an example of the method.

SERIES I. *Determination 2.*

Tare of globe exhausted = 198.22 grm. $T^{\circ} = 17.30^{\circ}$.

" " filled = 196.83 " $T^{\circ} = 17.30^{\circ}$.

3.	1'39	75'80	17'32	1'98
4.	1'37	75'78	17'40	1'96
5.	1'39	75'75	17'45	1'99
				1'97
SERIES II.				
6.	1'38	75'60	14'50	1'98
7.	1'39	75'60	14'50	2'00
8.	1'39	75'58	14'60	1'99
9.	1'40	75'58	14'61	2'01
10.	1'39	75'58	14'65	1'99
				1'99

Total average, 1'98 m.grms.

The quantity 1'98 m.grms. is then the correction sought, and this closely agrees with Lord Rayleigh's estimate of the value in the letter above referred to. Since in the work described in the preceding paper all the data required for the calculation were not recorded in every case, it will be impossible to apply this correction to each determination separately. But no sensible error can result if we add the correction to the average apparent weight of the hydrogen, easily calculated from the data given in the Table (*ante*, p. 32).

The total weight of the hydrogen burnt in the sixteen determinations as observed was 6'7029 grms. Add to this sixteen times the correction, or $16 \times 0'00198 = 0'0317$, and we obtain 6'7346 grms. for the corrected weight. The total weight of the water formed was 60'1687 grms. Hence we find by difference for the total weight of oxygen consumed in the combustions 53'4341 grms.; and the corrected atomic weight of oxygen is—

$$2(53'4341 \div 6'7346) = 15'869.$$

The probable error of this result is no greater than that of the "Total average" (*ante*, p. 32); for the value of the constant correction must be certainly known within the 1-50th of a m.grm. It is true that there are several variable elements which enter into the determination of this value, but they can all be estimated with far greater accuracy than the conditions of our problem require. We may therefore write as the present result of our work, $H : O = 1'000 : 15'869$.

Atomic weight of oxygen, $15'869 \pm 0'0017$.

If we compare this result with that of Dumas, as before, we have for the complete analysis of water,—

Percentage of oxygen after Dumas	$88'864 \pm 0'0044$
Percentage of hydrogen after final result	$11'193 \pm 0'0011$
100'057	

It would now appear that the close agreement before shown was a mere coincidence, and that there must have been a small constant error either in our own process or in that of Dumas. Where the error lies further investigation can alone determine; for although, after a careful revision of our work, we can discover no flaw, no one can be confident that such a constant error as has already appeared may not hereafter be found, and certainly can only be secured after repeated confirmations by essentially different methods. While, therefore, we feel bound to acknowledge without delay the cause of constant error which Lord Rayleigh has pointed out, we give our corrected result as subject to further revision. It has been suggested by Lord Rayleigh, in a "Preliminary Notice" of his work on the relative densities of hydrogen and oxygen, of which advance sheets have been received while

writing this note, that in our combustions the hydrogen may have been imperfectly burnt, especially as towards the last of the combustion it must have been greatly diluted (but with air). We have no decisive evidence on this point; but the whole course of our combustions assured us that this could not be the case. Duping the first stage of the combustion, when pure hydrogen was passing into the combustion tube, and while water was dropping into the condenser (Fig. 4), there would often be several minutes—during which the larger part of the water was condensed—when no residual gas whatever would be seen to escape, and the bubbling of the gas through the sulphuric acid at the bend of the U-tube made the least overflow perfectly evident. Again, the oxide of copper in the combustion tube was always reduced to a perfectly definite limit, leaving at least seven-eighths of the tube in which the black oxide was apparently wholly unchanged. Further, it is not probable that an error arising from the imperfect combustion of the hydrogen would have a constant value. The unconsumed residue must vary greatly with the conditions of the experiment; and such an agreement as that exhibited by the results could never have been obtained under such circumstances.

It seems unnecessary to add that every precaution was taken in our work which our experience could suggest, and that a great amount of labour was spent on such details which does not appear in the published results. Both the balances and weights employed were most carefully verified. The water formed by the combustion was tested, and the dissolved air taken into account. We mention these points because they have been noticed by correspondents; but many similar details which were worked out and set one side we have not thought it necessary to describe in our paper. In writing such a paper elementary principles must be assumed.

In adopting Regnault's method for weighing the hydrogen used in our determinations, we assumed with him that the glass balloon used in the work remained practically constant, whether exhausted or filled with gas. We never questioned this assumption, not only because we had the greatest confidence in all Regnault's work, but also because we knew that he had himself carefully investigated the behaviour of glass bulbs under pressure; and indeed he treats the subject fully in the paper immediately preceding his classical paper on gas density.* Moreover, we made with our apparatus a preliminary determination of the density of air, and obtained Regnault's number within the limits of the uncertainty in regard to the value of the force or gravity at this place. Regnault's values for the weight of 1 litre, not only of air, but also of nitrogen, oxygen, hydrogen, and carbonic dioxide, have been hitherto regarded as among the most trustworthy data of science. His determinations were all made by the method of counterpoise which we adopted in our work, and he used balloons of twice the volume of those we employed. When exhausted, the glass must have been condensed to an even greater extent than has been shown above; but no account whatever is taken of this shrinkage. As Regnault's constants have been universally used, it is obvious that Lord Rayleigh's correction must be applied to all determinations of gas or vapour densities hitherto made, and to all atomic weight determinations of any kind which involve the calculation of the weight of a measured volume of any gas or vapour. Except, however, in the case of hydrogen, the correction will be inconsiderable.—*Proc. Amer. Acad. of Arts and Sciences.*

A New Double Potassium and Sodium Carbonate.
 —L. Hugounenq and J. Morel.—The salt in question is a compound of double sodium-potassium carbonate and of sodium carbonate, each salt being combined with 6 mols of water.—*Bull. de la Soc. Chim. de Paris*, Vol. xlix., No. 9.

THE LABORATORY DRYING OVEN.

By A. J. BANKS.

IN laboratories where steam is used for the purpose of heating drying ovens, evaporating pans, &c., the water produced by the condensation of the steam is a frequent and troublesome annoyance. The supply pipes very often have to be carried a considerable distance before reaching the laboratory, and are, not unfrequently, exposed to strong draughts of air; hence, considerable condensation of the steam is brought about, and in conjunction with that produced by the expansion of the steam on entering

FIG. 1.

FIG. 2.

the oven, and the larger surface there exposed, the amount of water produced is a serious obstacle to the attainment of high temperatures.

With the object of overcoming this difficulty I have devised a modified form of water oven, which answers

admirably. Its construction will be readily understood from the accompanying drawing, which represents an ordinary drying oven with the bottom of the outer covering in the form of an inverted pyramid, provided with a gauge glass to indicate the height of the water, and a stopcock or valve for running off the same. The inlet pipe is placed immediately below the inner case, Fig. 1.

Where ovens of the ordinary flat bottom form are already fitted in the laboratory and supplied with steam a great deal of heat may be saved by passing the steam through a water separator immediately before entering the oven. By this means a large quantity of water held in suspension by the steam is removed.

I have lately had a water separator made according to my design, which I find answers this purpose very well. It consists of a copper cylinder 9 inches long, 4 inches diameter, and 1-16th inch thick, provided with a perforated diaphragm 3 inches from the bottom, to which five upright pieces of perforated copper plate are fastened, their upper ends being secured to the top of the cylinder. The central pieces, A, B, are each 1½ inches × 6 inches, and bent at an angle of 45°, so that the exhaust pipe, C, is surrounded by perforated plates. The remaining three plates are ¾ inch × 6 inches, and are inclined at an angle of 45°, with the diameters of the cylinder cutting each other at right angles, as shown in the section taken through M, N, Fig. 3. The inlet pipe is ½ inch internal diameter, and is

FIG. 3.

placed 2 inches from the top of the cylinder; the exhaust pipe has the same bore, and reaches 3 inches from the top. The gauge glass is of the usual form, provided with protection plates and a stopcock. A fixed indicator, D, shows the position of the diaphragm, above which the water should not be allowed to rise. The separated water may be drawn off by means of the stopcock, G, which may be so regulated that a constant level is maintained in the cylinder.

The drawings are not drawn to scale.

Fairfield, Liverpool.

ON A
PROBABLE ORTHO-QUINONE DERIVED FROM
ANTHRAQUINONE.

PRELIMINARY NOTE.

By W. H. RICHARDSON.

RECENTLY valuable additions have been made to our knowledge of the quinones, and a large share of the investigations in this direction we owe to Prof. Zincke and his students. One of the latest achievements in the Marburg Laboratory has been the preparation of derivatives of ortho-benzoquinone, a body hitherto unknown. By oxidation of tetra-brom- and tetra-chlor-pyrocatechine,

Zincke obtained the corresponding halogen ortho-quinones, and has furthermore shown that tetra-brom-ortho-benzoquinone is identical with the body described by Stenhouse as erythro-brom-pyrocatechine. With the hope of obtaining an ortho-quinone of the anthracene series, I have studied the action of various oxidising agents on alizarin, which may be regarded as the hydroquinone of a di-quinone—

which hypothetical body contains quinone groups in the para- and ortho-positions.

Oxidation in acid solution does not produce the desired effect; alkaline solutions of alizarin, however, are easily oxidised by the usual agents, but the best results are obtained by permanganate or bromine. The best conditions of experimenting have as yet not been determined, and I will defer the description of the actual oxidation until this has been done.

The alkaline solution containing a mixture of substances is acidified, whereby a fawn-coloured precipitate is produced. This precipitate I regard as a quinone or an ortho-diketone corresponding to alizarin, and for this assumption the following reactions may be adduced:—

- (1). By reduction in acid solution alizarin is reproduced.
- (2). Phenylhydrazine and its sulphonic acid produce characteristic substances, which are dye-stuffs; this speaks for the presence of two (CO) groups in the ortho-position (Fischer).
- (3). With aniline an anilide is formed.
- (4). The solution of the compound reacts easily with ortho-diamines (tri-amido-benzene and ortho-naphthylene-diamine-sulphonic acid).

The filtrate from this precipitate contains phthalic acid, which was recognised by conversion into fluorescein, and by the analysis of its barium salt.

Against the assumption that such a simple product of oxidation has been formed, the researches of Henriques may be quoted. He has shown that the naphthyl ring is destroyed by alkaline permanganate, benzene derivatives being formed, but further examination will show the real constitution of the body, and I have only published this note in order that I may secure the subject for complete investigation, and I hope before long to be able to give an exact description of this new compound and its derivatives.

Southwam, Halifax,

LECTURE APPARATUS FOR SHOWING COMBUSTION OF AIR IN AN ATMOSPHERE OF COAL-GAS.

By GEORGE CRAIG.

THE accompanying sketch represents a more simple and convenient form of apparatus than those in vogue for showing the combustion of air in an atmosphere of coal-gas, or other instances of a similar nature. It consists of a flask (6 inches in diameter) with a side tube on the neck for supplying the coal-gas, and with an orifice at the bottom, which is lined with asbestos, to act as a burner, and preserve the glass from cracking. The mouth of the flask is fitted with an india-rubber cork, the perforation through which is lined with ordinary cork well soaked in vaseline to make an air-tight joint and yet allow the glass tube ($\frac{1}{2}$ inch diameter) to move easily up and down.

To carry out the experiment, the glass tube is raised until it just projects through the orifice, the gas is turned on, and the apparatus inverted so as to fill it by displacement. When a strong smell of gas is perceived at the orifice

the issuing gas is lighted, and the apparatus restored to its original position. Caused by the draught of the flame, a current of air is drawn up the central tube, and of course burns along with the gas at the orifice. By simply lowering the glass tube the almost non-luminous air-flame may be shown burning in the interior of the globe. It is desirable to heat the flask gently before performing the

experiment, to prevent any subsequent deposition of moisture. When it is desired to stop the experiment the supply of gas is simply shut off, when the two flames, after a short time, go out quietly.

In exactly the same manner oxygen or chlorine may be shown burning in hydrogen gas.

The apparatus may be obtained from Messrs. Baird and Tatlock, Crown Buildings, Glasgow.

Ayrshire, N.B.

FURTHER INVESTIGATION ON THE ATOMIC WEIGHT OF COPPER.*

By THEODORE WILLIAM RICHARDS.

IN vol. xxii. of the *Proceedings of the American Academy of Arts and Sciences* there appeared a description of a new determination of the atomic weight of copper, based upon the precipitation of silver from a neutral solution of argentic nitrate by pure metallic copper. In the course of some further experiments it became necessary to ignite a portion of the silver from determination No. 5 of that series; and it was found that two grms. of silver lost four-tenths of a milligram. by this process. It is thus evident that 150° is not a temperature high enough to drive out all the water from the silver, and hence the results before given are incorrect by a slight amount. In this determination the weight of the silver was 3.39035 grms. after drying at 150° , hence its weight after ignition would have been 3.38975 grms. The weight of copper taken was 0.9987 grms., therefore the corrected atomic weight of copper would be 63.452 instead of 63.437.

* Contributions from the Chemical Laboratory of Harvard College. From the *Proceedings of the American Academy of Arts and Sciences*, vol. xxiii.

Unfortunately, all the silver formed in the other determinations had been employed in testing for the presence of copper; hence it was impossible to determine whether the other samples would lose water on heating in a similar manner. It seemed, therefore, desirable to make a new series, using samples of pure copper, prepared from the ores of different localities. Should the result be the same in each instance we should have a very strong proof, not only that the copper used in each case was pure—because the different samples would probably contain different impurities—but also that the atomic weight of copper is a perfectly constant quantity.

The method used was exactly that of the previous paper, although more difficulty was found in keeping the solution below zero for twenty-four hours than was the case before, because of the warmer weather. Several determinations had to be rejected because the temperature rose above zero, and copper was precipitated with the silver. Upon splitting open the fine crystalline plates of silver precipitated in these rejected experiments, a light-green precipitate of basic cupric nitrate was found adhering to the inner surface, which could not be removed by continued washing with cold water. The presence of this precipitate explains the admixture of copper with the silver precipitated above zero, and points at once to the mechanism of the chemical action.

When copper is placed in a solution of argentic nitrate, two reactions take place, and the temperature regulates the predominance of one or the other. The chief reaction is the simple one ordinarily written; it alone is active between 0° and 5° , and it is the chief one even at 100° . The secondary reaction, which is active at 100° but which entirely ceases below 0° , may perhaps be written thus—assuming that the basic nitrate has the formula usually assigned to it:—

Evidently in this reaction the copper precipitates only one-half of its equivalent of silver. It will be remembered that an evolution of nitrous fumes was previously observed when the temperature rose above the freezing-point.

The argentic nitrate used in the new series, was prepared as before, except that even greater precautions were taken to insure its purity by successive crystallisations and fusions.

Two samples of copper were used, one from Lake Superior, the other from Germany. For the purification of the former the sample was dissolved in sulphuric acid, with the addition of nitric acid; the solution was evaporated to dryness, and the solid heated over asbestos in a porcelain dish until the fumes of sulphuric acid ceased coming off. The cupric sulphate was now dissolved in water, crystallised twice, and the diluted solution of the last crystals boiled and shaken with a little

potassic hydrate for three hours. The solution was now filtered, and the cupric sulphate was crystallised several times from hot water. Finally, the solution of the last pure crystals, strongly acidified by sulphuric and a little nitric acid, was decomposed by the current of a Bunsen cell, and the chemically pure copper deposited on thick platinum foil.

The second example of copper was prepared from German cupric oxide in a similar manner except that the sulphate was crystallised a greater number of times. In this connection it may be mentioned that, of many samples of German cupric oxide tested, not one was found which did not contain a comparatively large amount of arsenic. In the case of many samples, after several reductions with pure hydrogen and oxidations, the arsenic will actually sublime off as arsenious oxide; and a quantity of the substance was collected in this manner.

The method of cleaning the copper was similar to that previously adopted; it was treated in succession with dilute potassic hydrate, dilute sulphuric acid, and a very large amount of water, and then dried and reduced by pure hydrogen.

The silver which was obtained by precipitation from the pure argentic nitrate was first washed and dried at 150° , and weighed as before; and was then heated to incipient redness, and weighed again. The loss of weight by this process varied with the different samples between three-tenths of a milligram and one milligram. The Gooch crucible and asbestos mat subjected to the same treatment did not lose an appreciable quantity. The results were calculated for the weight of silver both before and after ignition, and it will be noticed that the first column of results corresponds almost exactly to the results given in the previous paper. The silver was in each case tested for copper, and no trace was found.

The average of these two series is 63.450 , with greatest variations of $+0.002$ and -0.003 , and a probable error of ± 0.0006 . The average of the results calculated from the weight of silver dried at 150° is 63.436 , while the results published in the preceding paper gave 63.437 .

The complete concordance of these results with each other, and with the previous value above referred to, would point strongly to the following conclusions:—

First, that the copper used in each case was absolutely free from metallic alloy; for manifestly, the three entirely different samples would be likely to contain different impurities, or at least different amounts of the same impurity. The copper was tested for sulphur with the greatest care by solution in nitric acid and treatment with baric chloride, and no trace of cloudiness was perceptible. That the copper was *absolutely* free from impurity is not contended; only, that it did not contain a weighable amount of impurity in one gram, the amount used in each experiment. It is manifest that attempts to purify the copper beyond this limit would be labour thrown away, and would produce no effect upon the

atomic weight. For example, one-tenth of a milligram is a very large amount of foreign material to suppose existing in a gram of copper purified with such care; but this large amount would only change the atomic weight five units in the third decimal place—a quantity which is of no consequence when the atomic weight is in doubt three units in the first decimal place.

Another and still more positive conclusion reached by these results is that the atomic weight of copper is a constant quantity with reference to nitric acid and silver. If copper had a variable atomic weight it would surely appear in specimens taken from such widely different sources. This conclusion still remains in force, even supposing there be a constant error in the process, for the constant error must affect all the results equally, and could not possibly equalise unlike results.

A third conclusion, pointed out by the determinations, is that the argentic nitrate was the normal compound, and quite pure; for it will be remembered that two entirely different samples had been used in the course of the work.

There is but one point which remains to be considered, and that is the existence or non-existence of a constant error in the reaction. That this is by far the most important point in the whole discussion it is unnecessary to state. Whether there be such a constant error future investigations may show; for the present, it is sufficient to say that it is extremely difficult to see where such an error might creep in. The whole reaction is so simple and so sharp that the probability of error is reduced to a minimum, and in every case any possible cause of error has been guarded against.

Professor Cooke, under whose direction the whole investigation has been conducted, suggested that similar experiments be made, using argentic sulphate instead of the nitrate; but after a large number of trials this was found to be impracticable: first, because the solution has a much higher freezing-point than that of the nitrate; and secondly, because the solution was necessarily so dilute on account of the slight solubility of argentic sulphate, that the complete precipitation of the silver required a much longer time, giving more opportunity for secondary reactions. The silver was always accompanied by a very slight admixture of some basic cupric sulphate; and hence this method, which, if successful, would have been able to throw much light on the question of a constant error in the previous results, had to be abandoned.

NOTICES OF BOOKS.

The Laboratory Guide; a Manual of Practical Chemistry for Colleges and Schools, specially arranged for Agricultural Students. By A. H. CHURCH, M.A., F.R.S. Sixth Edition, Revised and Enlarged. London: Gurney and Jackson (late Van Voorst).

WHEN a work has passed successfully through the ordeal of six editions, and is still regarded with approval by competent judges, the task of the reviewer is to a great extent anticipated. The "Laboratory Guide," however, has grown from 174 pages to 286, and contains not a few emendations and additions which it may be useful to point out.

Thus we now find introduced the methods of Ruffe and of Kjeldahl for the determination of nitrogen. In the analysis of milk the method of Adams is recommended where a strict determination of fatty matter is aimed at. For the estimation of fats in butter we have the processes of Kœttstorfer, the "rapid" saponification, Reichert's and Hehner's method.

For the determination of the true albumenoids Mr. Church gives the preference to the phenol method as against the tannic, the ferric acetate, and the lead acetate processes.

The analysis of water is explained at considerable length, it being, however, pointed out that gas analysis and the search for rare constituents do not fall within the scope of the work. The determination of nitrogenous organic matter is given according to the Wanklyn, Chapman, and Smith process. The author directs the amounts of ammonia obtained to be entered as albumenoid ammonia, a term which, though inexact, is generally understood.

A brief notice is given of the "biological test" for waters, of the value of which the author seems doubtful.

In the separation of iron and aluminium in soils, coprolites, &c., the author determines the iron volumetrically, and deducts its calculated quantity from the joint weight of the two bases. It would have been interesting to see his opinion on the new trimethylamine process.

We notice with satisfaction the introductory remark that, though the facts and the laws of chemistry are the same for all students, yet they may and should be illustrated in a different manner, according to the objects which different classes of students have in view. Thus the agricultural student "would have the laws of diffusion illustrated to him by the processes which go on in the soil and in the plant; the medical student, on the other hand, would study the same laws as they work in the liquids and gases concerned in the functions of the human body." Thus the study of chemistry may be made, at the same time, both general and special.

The "Laboratory Guide" is in no danger of losing its pre-eminence as the most suitable manual for agricultural students.

The Manufacture of Potassium Chlorate and other Chlorates. ("Die Fabrikation von Chlorsaurem Kali und anderen Chloraten.") By K. W. JURISCH, Ph.D., Privat Dozent in the Royal Technical High School of Berlin. Berlin: R. Gaertner.

THE author of this useful work has evidently a thorough acquaintance, practical and theoretical, with his subject, and he expounds the results of his experience in a very clear and comprehensive manner. In the first section we find a general notice of the history of potassium chlorate, its properties, its industrial applications, formation, and preparation.

According to Kopp this compound has been obtained as far back as the 17th century, though it was then confounded with saltpetre. Berthollet first recognised its nature and composition in 1786 to 1788., or, according to one authority, as early as 1785. The first indications for its preparation on a commercial scale were due to Liebig.

The decomposition of potassium chlorate by heat has been the subject of no little research. It has been generally observed that the gas given off on heating the chlorate, whether alone or along with manganese, is contaminated with chlorine, and that the residue contains, along with potassium chloride, a little potassium oxide. This latter fact was ascribed by some authorities to the presence of a small impurity of potassium nitrate. Vulpus, however, showed that even in the total absence of nitrates the residue has an alkaline reaction. L. Scholvin, who has made a thorough investigation of this question, suggests that there is formed during the fusion of potassium chlorate a lower combination of chlorine and oxygen.

The poisonous character of potassium chlorate is brought into prominence. The corresponding sodium salt is so much less dangerous that the poisonous character of the potassium salt is ascribed to the general nature of the potassium salts rather than to the specific action of chloric acid.

The modern methods for its manufacture are developments of the original process devised by Liebig, which consists in first preparing a solution of calcium chlorate, which is then decomposed by potassium chloride.

In the second chapter we find a detailed description of

the apparatus and of the progress of the manufacture, illustrated with designs drawn to scale. Certain modifications are involved, according as the supply of chlorine gas is obtained by the Weldon or the Hurter-Deacon process.

We notice with pleasure that the author in giving the densities of liquids in degrees Twaddell, explains for the benefit of his countrymen how readily these degrees are translated into the corresponding degrees of direct specific gravity,—an advantage which the scale of Beaumé is very far from possessing.

The following chapter, the chemical investigation of the process, opens with analyses of the raw materials and a statement of their cost. For the chlorine gas prepared on Weldon's process the author admits an average strength of 25 per cent by volume, whilst the Hurter-Deacon gas ranged between 3 and 11 vols. per cent. But into the particulars of this admirably elaborated section space does not allow us to enter.

A technical and economical criticism of the manufacture comes next. The author points out that chlorine and potassium chloride being the costliest materials, their full utilisation is a question of prime moment. Fuel comes only in the second rank, whilst labour, repairs, and lime are relatively unimportant items. The theoretical yield of chlorate is 148 parts per 100 parts of potassium chloride at 90 per cent. The average of the years 1873-76, however, did not exceed 104.7 per cent. In the years 1877-80 the proportion rose to 110.1 per cent. Dr. Jurisch finds that in the consumption of acid the Deacon process has a decided advantage over that of Weldon.

The production cost per ton chlorate in England the author calculates at £31 4s. 6d. by the Weldon process and £28 3s. 4d. by the Hurter-Deacon. In Germany the cost of the Weldon process is greater than in England, but by the Hurter-Deacon method it is calculated as less by one-fourth. In Germany it appears more advantageous to convert the hydrochloric acid into potassium chlorate than to sell it as such.

The remaining chapters discuss the magnesia process (which yields a better return than the lime process per 100 parts of potassium chloride consumed, but which encounters collateral difficulties), the manufactures of sodium, lithium, and barium chlorate, and finally the statistics of the manufacture.

The appearance of this work is an important and most welcome addition to the technology of our greater chemical industries.

Technical Education from a Working Man's Point of View.

Is Technical Education a Device of Employers?

A Working Mechanic's View of Industrial Education.

A Workman's Wants.

Is Technical Education for the Many or the Few?

Our Neighbours and Ourselves.

A Question for Parents. What is Technical Education?

A Question for Employers.

THAT our national industrial position in these days is unsatisfactory needs no demonstration. That our system of education, if system it may be called, is inferior to that of many countries, and especially of those nations which are our chief rivals, is also admitted by all who can judge the tree by its fruits. And there is a growing conviction that the second of these shortcomings is largely responsible for the first. In this feeling we must avow our conviction that a great part of the assertions and the arguments to be found in the pamphlets and leaflets above mentioned are true and cogent, and that they earnestly call for practical attention. The writers in question do nowhere allege that our defective or unpractical education is the sole cause of industrial depression. They admit that our manufacturers and merchants have been too little heedful of the wants of their customers, that they have insisted too stringently upon larger profits and short credits, and, in short, have gone on the "take it or leave it" principle, thus allowing their foreign competitors to introduce the thin end of the wedge. They further concede that our commercial travellers and agents have been less willing or less able to ingratiate themselves with the people with whom they have to do business.

The writers in question, however, make no mention of our defective patent laws, which allow an alien to uphold a British patent without even working it on British ground, whilst a British subject obtaining a patent abroad loses it unless he works it abroad. The regrettable fact that so many alien clerks, foremen, &c., are employed in British manufactures is due not solely to any superiority on their part, but to causes which to expound would involve a digression.

But the real question now before us is what are we to do to bring up our technical and scientific education at least to the level of our neighbours? Additional expenditure and additional taxation will not of necessity effect the end desired. A cripple in the right road will beat the fleetest racer in the wrong one, all whipping and spurring notwithstanding. Now are we in the right road, or are we about to get into it? One only of the leaflets before us seems to touch upon this phase of the subject at all. The author of "Handy Hands and Observing Eyes" notices, in a very modest and quiet manner, the absence in our education—high class and low class alike—of any systematic culture of the faculty of observation. He declares our present system a "mere routine of reading and memory," and demands something "less bookish and more intelligent." But in not one of these documents is there any reference to the main difference between our modern British educational system and that which prevails, e.g., in Germany. This difference lies in our unhappy notion of "payment by results" and in our ever-recurring examinations. Here, we believe, is the root of our inferiority. The properties which come to the front in an examination—verbal memory, the power of reproducing what has been swallowed in authorised language—are precisely the properties which do not lead to success in practical life, still less to eminence in Science. No examiner can test the power of a student to observe accurately and searchingly and to draw correct conclusions from the phenomena observed. Consequently our system favours and produces talkers rather than workers.

One of the writers whose works lie before us protests against blindly following foreign systems, unsuited to our national conditions. But is not competitive examination a blind following of the Chinese, among whom its unhappy results may be plainly seen in general stagnation?

In the pamphlets before us, as well as in the Bill on Technical Education which Parliament will before long

have to discuss, we see no indications of any improvement. For anything we can see to the contrary payment by (pseudo) results, examinations, and cram will flourish in the technical schools. The teaching will be under the management of the School Boards, bodies generally composed of the nominees of the religious denominations or of the political factions in each district. Nor is it free from the influence of the Department of Science and Art, a body to which we object, amongst other reasons because it is to a great extent, and we believe in virtue of a statute in the lands of military men. The main task of the true educator is to develop the powers of every mind coming under his charge, each in its own direction. But the main task of the military man is to reduce everything to one uniform, stereotyped pattern. It provokes a smile on the Continent that the nation which entrusts its army and navy to the management of civilians should, in return, place its schemes for higher education in the hands of soldiers.

CORRESPONDENCE.

ON THE COLORIMETRIC DETERMINATION OF SULPHUR IN IRON AND STEEL.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS (vol. lviii., p. 41) there appears an article by Arnold and Hardy, on "New Methods for the Estimation of Sulphur in Iron and Steel-making Iron," in which the authors give their experience of Parry's colorimetric method described by me (CHEMICAL NEWS, vol. lvi., p. 13), which is to the effect that "under the prescribed conditions the colour" obtained (say from a steel containing 0.03 per cent S) "is a very decided precipitate, and that consequently accurate comparison is impossible."

Speaking from personal experience, extending over a period of two years (during which time I have employed Parry's colorimetric method for the determination of S in iron and steel, ranging from as low as 0.02 to as high as 0.20 per cent and over), I have found the method to give very concordant and good results, as proved by their agreeing, within experimental error, with those obtained by independent chemists and the Barium Chloride method.

The precipitate obtained by Arnold and Hardy in working the method may be due to one or more of the following causes, viz.,—

- (A) The lead acetate solution employed was too strong.
- (B) The cylinder containing the acetate solution became heated.
- (C) The acetate solution, after evolution of gas had ceased, was allowed to remain for too long a period before comparison.

It is true that with careless manipulation a precipitate is formed, but with the strict observance of the above precautions, and above all *practice*, this is prevented.

Concerning the colorimetric method described by Arnold and Hardy, I am of opinion that it is nothing more or less than a *modification of Parry's colorimetric method* described by me. Practically, therefore, Parry has the *prior* claim of having first adapted the employment of a lead acetate solution as the basis of a colorimetric method. But he informs me that he considered it merely a modification of Frankland's method for the determination of lead in water. It is therefore, strictly speaking, not a *new process* in the ordinary sense of the word. And further, that he considered it hardly worth publishing, as any chemist may work out such a modification.—I am, &c.,

J. JAS. MORGAN.

The Laboratory, Ebbw Vale,
July 31, 1888.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of emperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 3, July 16, 1888.

Observations on the Recent Communications of M. Sabatier on Hydrochloric Copper Chloride and on Hydrochloric Cobalt Chloride.—M. Engel.—The author complains that although M. Sabatier admits his priority, yet that he has erroneously sought to explain the discrepancy between his formula and that of M. Engel by asserting that the latter had analysed a partially decomposed specimen.

The Elementary Composition of Crystalline Strophantine, extracted from *Strophantus Kombé*.—M. Arnaud.—The composition of strophantine is $C_{31}H_{48}O_{12}$, and it appears, therefore, as the next higher homologue of ouabaine, $C_{30}H_{46}O_{12}$. These two substances, both free from nitrogen, seem to have in their constitution a common central nucleus, which is perhaps the same with an entire series of heart poisons.

Influence of the Temperature of Fermentation on the Production of the Higher Alcohols.—L. Lindet.—The proportions of the higher alcohols are substantially the same at different temperatures.

Bulletin de la Société Chimique de Paris.
Vol. xlix., No. 9.

On the Metapyrazolones of Pinner and Lifschütz.—Ed. Grimaux.—The alleged metapyrazolone is the body generally known under the names glycol-urea or hydantoine.

Preparation of Hydriodic Acid.—A. Etard.—The author proposes the use of a new apparatus, which is here figured.

Researches on the Optical Isomers of Cinchonine.—E. Jungfleisch and E. Léger.—The authors explain a treatment based upon a very small number of facts: the separation of the bases respectively soluble and insoluble in ether. In the soluble bases, separation of cinchonine as hydrochlorate and of cinchoniline as dihydriodate. Among the insoluble bases there is effected a separation of the oxycinchonines based upon their solubility in weak alcohol, and of cinchonibine as succinate, and of conchoni-fine as hydriodate.

A Pseudomorphosism of Acerdese. Artificial Production of Pyrolusite.—A. Gorgen.—The nature of this paper appears sufficiently from the title.

Researches on Phosphorescent Hexagonal Blende.—A. Verneuil.—Already noticed.

On Nitro-nitroso-resorcine.—M. de la Harpe and F. Reverdin.—This compound is obtained by introducing gradually a refrigerated mixture of 1 mol. nitro-resorcine, 1 mol. caustic soda dissolved in 10 parts of water, and 1 mol. sodium nitrite in aqueous solution into an excess of dilute refrigerated sulphuric acid. Yellow flocks are precipitated, having the composition—

No. 10.

On Chydrazine or Ammonia Protoxide.—E. J. Maumené.—(To the name of this compound is appended the note:—"Pronounce *ci*; *c* signifies 3 equivalents of hydrogen"). The normal action of ammonium oxalate and permanganic acid may be easily obtained by bringing equal weights of the two bodies into contact. He takes, however, 111 grms. of the oxalate, 158 grms. of potassium

manganate, and 40 of SO_2 . These ingredients are mixed in the author's "mixer" ("mélangeur"). The acid to be combined with the "chydrazine" is placed in the receiver.

Separation of Calcium from Barium and Strontium.—Professor Kupferschläger.—The author, after criticising other methods, describes his own process. The mixture of calcium, barium, and strontium carbonate is treated with very dilute nitric acid and evaporated to dryness. The residue is taken up in pure water, and the solution, filtered and quite neutral, is evaporated to complete dryness. The three nitrates which constitute this product are successively exhausted by four successive small portions of absolute alcohol, each time a little more ethereal than the former. This is done in a small well-stoppered flask, which is often shaken, the solutions are filtered after standing long enough to become clear, not longer. When the last portion of ethereal alcohol leaves nothing on spontaneous evaporation the calcium nitrate is separated from the two others. These, after being well dried, are dissolved in water and to the solution placed in a small tall narrow glass is added solution of potassium dichromate, saturated in the cold; in this manner the barium is thrown down on chromate. The precipitate, after washing with water containing a little alcohol, is then heated with sulphuric acid to convert it into barium sulphate. The liquid containing the strontium is mixed with dilute sulphuric acid and heating moderately, so as to throw down the strontium sulphate.

The Purification of Mercury.—J. M. Crafts.—The author effects the purification by passing air through the mercury for forty-eight hours. The impurities, zinc, lead, tin, &c., collect at the top of the tube in the form of a black powder. The removal of traces of silver and gold is not necessary for mercury intended for filling barometers and similar instruments. These impurities do not affect the density of the mercury, nor alter the appearance of the meniscus. The author considers that if pure air has any oxidising action upon pure mercury it is so slight as to be scarcely appreciable. Platinum in thin foil is not attacked by mercury in the cold, but on prolonged boiling the platinum is attacked, the greater part remaining in suspension as a black powder.

The Resistance to Light of Colouring-matters fixed upon Tissues.—Jules Joffre.—The author proposes methods of testing the permanence of dyed tissues on exposure to light. The methods employed, the precautions to be taken, and the fact that the action of light is intensified by moisture, are not unknown to colourists.

Composition and Combustion-heat of Coal of the North of France.—M. Scheurer-Lestner.—The author's results are given in the form of tables.

Chlorine and Cyanogen.—E. Allary.—Dumas, in one of his most interesting memoirs, resolved the atomic weight of chlorine into a polynome of the following form. $\text{Cl} = 35.5 = 19 + 16.5$. The author has arrived at the same point by setting out from a different point of view, the isomorphism of potassium chloride and cyanide. He suggests that chlorine may be a compound of fluorine and oxygen, perhaps intimately united to $\text{H}/2$.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 1.

Detection of Fusel in Spirits.—Uffellmann (*Zeitschrift für Hygiene*), pours 250 c.c. of the spirit into a $\frac{3}{4}$ litre flask, adds 100 c.c. of ether, shakes up well, adds sufficient water to separate the ether, draws off the ethereal liquid, shakes up afresh with 100 c.c. ether, unites the ethereal extracts, lets evaporate, dissolves the residue in 40 c.c. ether, adds a few c.c. of fresh green solution of methyl violet (dissolve 1 part methyl-violet in 100 water and add hydrochloric acid at 2 per cent until the liquid turns green), shakes, and pours into a graduated tube, 2.5 c.m. in diameter. The ether evaporates. As soon as a blue

colour is perceived and the first indication of the methyl-violet absorption at D is detected with the spectroscope, he reads off the quantity of ether still remaining. Each 10 c.c. of the liquid contain 0.2 c.c. amyl alcohol, which occasions the blue colour.

Distinction between Horse-flesh and Ox-flesh.—James Bell.—From the *CHEMICAL NEWS*.

On Cacao and its Preparations.—P. Zipperer.—A prize essay, the particulars of which are not given.

Analysis of the Peptones.—Guido Bodländer.—This paper does not admit of a useful abstraction.

Examination of Peptonising Ferments.—E. Geisler and A. Kremel.—For the contents of this memoir we must also refer to the original, or to the *Pharmaceut. Central-Halle* and the *Pharm. Post*.

Determination of Carbonic Acid in Inhabited Rooms.—R. B. Warder.—From *Annual Report of State Board of Health of Indiana*.

Bacteriological Examination of Soils.—C. Fränkel.—This memoir does not admit of useful abridgment, and the reader is therefore referred either to the *Zeitschrift* or to the *Zeitschrift für Hygiene*.

Chemical Test for Cholera Bacteria.—Bujwid has recently referred to the colour of the culture-liquids on admixture with hydrochloric acid. Dunham remarked that the presence of peptone in the culture liquid was essential for the success of the reaction. Josef Judassohn now states that the cholera-red reaction is obtained in culture liquids free from peptone, and that an abundant growth of cholera-spirilla may exist, though the reaction does not succeed. Purity of the culture and an abundant supply of oxygen are needed to produce the cholera-red. F. Cahen takes the suspected colonies from a plate-culture, puts them in alkaline culture solution with the addition of litmus, and leaves them at a temperature of 37° . If the next morning the liquid is found colourless *Spirillum cholerae* is present.

Fatty Acids in Soap.—A. Bertschinger takes 100 c.c. of a solution of 25 grms. of the soap in 500 c.c.; decomposes it on the water-bath with 25 c.c. normal sulphuric acid, washes the fatty acids upon a tared filter, dries along with the filter in a beaker, and weighs. The filtrate and washings serve for the determination of total alkali.

Quick Method for Determining Acetic Acid in Acetates.—A. Sonnenschein (*Chemiker Zeitung*) takes 5 grms. of the powdered sample of sodium acetate and dissolves them in water in a beaker with the aid of heat, and makes up in a flask to 250 c.c. If carbonaceous matter is present it is filtered off before making up; 50 c.c. of the clear liquid are mixed with three drops of phenacetoline in a porcelain capsule. If a red colour is produced it is titrated with hydrochloric acid until it turns to a yellow. The acid consumed is calculated as sodium carbonate. Two drops of methyl-orange are next added, titrating until redness appears. The acid consumed is calculated as acetic acid or sodium acetate. Acetate of lime gives a coloured solution, and must be treated with carbonic acid, boiled with animal charcoal, filtered, and made up to a known volume.

Examination of Glue.—R. Kissling (*Chemiker Zeitung*).—This paper requires the accompanying illustrations.

Examination of Commercial Quinine Sulphate.—De Vrij.—From the *Pharm. Journal and Transactions*.

The Acidity of Human Urine.—E. von Brücke (*Monatshefte für Chemie*) denies such acidity, as it does not turn a solution of congo-red blue.

Determination of Urea.—P. Cazeneuve and Hugouenq.—From the *Bulletin de la Soc. Chimique*.

Rautenberg's Titration of Urea with Mercuric Nitrate.—This process, which is condemned by Pfüger, is defended by Pfeiffer.

Reaction of Animal Fluids.—C. Wurster mentions that in presence of ammoniacal salts congo-red reacts slowly even with mineral acids, and far more imperfectly with organic acids and carbonic acid.

Total Nitrogen in Urine.—L. Garnier.—From the *Journal de Pharmacie et Chimie*.

A New Reductive Substance in Urine.—J. Marshall.—From the *American Journal of Pharmacy*.

Alkaline Solution of Bismuth as a Reagent for Sugar in Urine.—Nylander's modification of Böttger's process is warmly commended by C. le Nobel.

The Multiplier for the Determination of Sugar in Urine.—Roberts.—A controversy for which the editor refers to *Pflüger's Archiv*.

Detection of Aniline, Acetanilide, and Paramidophenol in Urine.—F. Müller.—For the detection of aniline is mentioned the intense blue colour produced on adding dilute hydrochloric acid, kairine, and potassium nitrite.

New Substance in Urine analogous to Indoxylsulphuric Acid.—J. Thormaehlen.—The author attempted to isolate this compound from the urine of horses, but did not succeed.

Detection of Small Quantities of Digestive Ferments in Animal Liquids.—For this paper we must refer to the original.

Reagent for Albumen.—G. Mya proposes potassium nitroprusside, the urine being previously acidified with acetic acid.

Detection of Arsenic.—This memoir cannot be reproduced without the accompanying figure.

The Atomic Weight of Fluorine.—O. T. Christensen.—The author finds the value 18.94 (O=15.96) or 18.99 (O=16).

Atomic Weight of Cerium.—H. Robinson.—From the *CHEMICAL NEWS*.

Part 2.

Volumetric Determination of Molybdc Acid and of Lead.—Carl Schindler.—If solutions of ammonium molybdate and of lead acetate are brought in contact there is formed a white precipitate of lead molybdate, which quickly settles if heated. Chatard has already utilised this reaction for the gravimetric determination of molybdc acid. The author applies it for a volumetric determination of both bodies, using an aqueous solution of tannin as indicator. If a drop of this solution is allowed to touch a solution of ammonium molybdate, placed upon a white porcelain plate, there appears, according to the concentration of the molybdate solution, a colouration blood-red to yellowish, distinctly visible at a dilution of 1 : 400,000, whilst the insoluble lead molybdate gives no colour, and lead acetate, if very strong, gives merely a faint greenish-yellow colour which cannot be confounded with that just mentioned. If we have a solution of ammonium molybdate and precipitate it by the successive addition of solution of lead acetate, a drop of the liquid gives the above reaction as long as molybdc acid remains in solution. Inversely a solution of lead precipitated in a corresponding manner with solution of molybdate does not give this reaction until all the lead is thrown down and molybdc acid is present in slight excess. For the titration the following solutions are required:—(1) Solution of lead acetate, prepared as follows:—40 to 50 grms. lead acetate are dissolved in water with the addition of a little acetic acid. The solution is let down to 1 litre and standardised with pure ammonium molybdate, which contains 81.55 per cent molybdc acid. (2) A solution of ammonium molybdate, of which 1 c.c. = 1 c.c. of the lead solution, 20 grms. of commercial ammonium molybdate are dissolved in 700 to 800 c.c. of water. Ammonia is added until the slight turbidity dis-

appears and the liquid is standardised to Solution 1. (3) Dilute solution of tannic acid in water; about 0.1 grm. to 30 c.c. It should be prepared fresh for every series of experiments. The analysis is executed as follows:—The molybdc solution, slightly acidified with acetic acid, is placed in a beaker and boiling water is added until the liquid reaches the volume of 300 to 400 c.c. Lead solution is then dropped in until the molybdc acid is entirely precipitated and a small excess of lead remains in solution. It is stirred and let settle for a moment. Then a large drop is taken from the upper layer of the solution by means of a fine dropping tube and brought in contact with a drop of the tannin solution upon a porcelain plate. If sufficient lead has been added there appears no colour. One-tenth c.c. of the titrated molybdc solution is now added, stirred, let settle, and tested again with the tannin solution. This is repeated until a drop produces a distinct orange colour. The volume of the molybdc solution consumed is deducted from that of the lead solution, and the molybdc acid is calculated from the remainder. In determining the lead in a liquid the procedure is analogous. The liquid containing the lead is slightly acidified with acetic acid, and molybdc solution is added until a drop of the liquid gives the molybdc reaction. If the quantity to be determined is not approximately known it should be ascertained by a preliminary experiment. A small excess of lead solution (about 0.5 c.c.) is used, titrating back with molybdc solution. The tannin drops are best placed upon a porcelain plate with depressions.

Volumetric Determination of Phosphoric Acid.—Carl Schindler.—For the execution of this process we require the following solutions:—(1) Molybdc acid. To 1 litre of molybdc solution prepared as usual there are added 30 c.c. of a solution containing 500 grms. citric acid per litre. (2) Strong solution of ammonium nitrate containing 750 grms. NH_4NO_3 per litre. (3) Dilute solution of ammonium nitrate containing 100 grms. NH_4NO_3 per litre and 10 c.c. HNO_3 . (4) Magnesia mixture (Fresenius). (5) Solution of lead of which 1 c.c. represents 0.04 grm. P_2O_5 . It is prepared by dissolving 55 grms. lead acetate in 1 litre water and standardising with any solution of phosphoric acid of known strength. (6) Solution of ammonium molybdate of which 1 c.c. corresponds to 1 c.c. of the lead solution. It is obtained by dissolving 25 grms. ammonium molybdate in 1 litre water and standardising with Solution 5. (7) Solution of tannin. About 0.1 grm. tannin is dissolved in 20 to 30 c.c. water. This solution is always to be prepared afresh before use. The analysis is performed as follows:—50 c.c. of the nitric solution of phosphoric acid, representing 0.5 grm. of the substance, are mixed with so much of No. 2 that the liquid, after precipitation, contains—

$$\text{Vol. of No. 2} = \frac{\text{Vol. of phosphoric acid} \div \text{Vol. of No. 6}}{2}$$

So much of No. 1 is then added that 100 c.c. come to 0.1 grm. P_2O_5 . The whole is then heated on the water-bath to about 58°, let settle for five to ten minutes, and the supernatant liquid is filtered off. If the filtrate is heated to a higher temperature there generally appears a further deposit of ammonium phosphomolybdate, but so minute in quantity that it may be neglected. The precipitate is washed three or four times by decantation with about 50 c.c. of dilute solution of ammonium nitrate and dissolved in a beaker with liquid ammonia at 3 per cent. The solution is then placed in a 1-litre flask, adding the rinsings of the filter (with the same solvent), 10 to 20 c.c. of the magnesia mixture are added, the flask is filled up to the mark, shaken up, and the liquid is filtered through a dry filter. Of this filtrate 50 c.c. are measured off, the liquid is made up to 300 to 400 c.c. with boiling water, and so much of the lead solution (No. 5) is then added from a burette that there may remain in solution a small excess of the lead (0.5 to 1 c.c.), titrating back with the ammonium molybdate solution.

New Method of Determining Ashes.—Ludwig Reese.
—The author has constructed a small apparatus, by means of which a current of hot air is passed over the heated substance; all swelling up or frothing is either prevented or made harmless, and the incineration is quickly effected. The construction of the apparatus cannot be explained without the accompanying figure.

Chemical Works, recently erected, on Canal side, Clayton, 3 miles from Manchester, enclosing 2500 yard of land with a large Wharf. Water free, rates very low. Also a plot of land adjoining. Will Sell or Let.—Address S., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1498.

ON THE DETERMINATION OF SULPHUR IN IRON AND STEEL.

By J. JAMES MORGAN.

To the best of our knowledge, and as far as our experience extends, the numerous methods employed by the chemist for the determination of sulphur in iron and steel resolve into and are founded upon two well-known principles, viz., that (A) When iron or steel containing sulphur is dissolved in hydrochloric or sulphuric acids, sulphuretted hydrogen is evolved. (B) When iron or steel containing sulphur is treated with an oxidising reagent, such as nitric acid, it is converted into sulphuric acid, which is subsequently precipitated as barium sulphate.

It will better serve our purpose—viz., that of criticising—and also simplify matters if we subdivide the methods based upon Principle A into three classes, according to the after treatment of the sulphuretted hydrogen, viz.,—A I. In which the sulphuretted hydrogen is oxidised into sulphuric acid, with subsequent precipitation as barium sulphate. A II. Where a metal is precipitated as a sulphide from the solution of its salt, preferably a copper salt, by passing the sulphuretted hydrogen evolved through, with the collection of the metallic sulphide and subsequent conversion into oxide by ignition. A III. A colorimetric method, in which the sulphuretted hydrogen is passed through the solution of a metal and the colour compared with that obtained on treating a "standard" in a similar manner.

Methods Based on Principle A.

Class A I.—Where the sulphuretted hydrogen is oxidised into sulphuric acid by means of bromine, &c., and subsequently precipitated as barium sulphate.

Class A II.—In which the sulphuretted hydrogen is conducted through a solution of copper sulphate, lead acetate, or a cadmium salt, and the resulting metallic sulphide collected, and in some instances converted into oxide by ignition.

The above two methods do not call for any special remarks. In point of accuracy there is very little to choose between them, but perhaps A I. may be said to be the better of the two. As regards the time required for their performance A II. has a decided advantage, being more expeditious.

Class A III.—As an illustration of this class we shall take Parry's colorimetric method, full details of which appeared in the *CHEMICAL NEWS* (vol. lvi., p. 13).

Our experience of this method is that it furnishes very good results. We may here remark that the non-uniformity in composition of the steel employed as a "standard" is felt in a more marked degree than in the colorimetric determination of combined carbon. The employment of permanent standards is recommended as a remedy, but we are adverse to the same, not deeming them satisfactory. We have therefore no other alternative than to make the best of a bad job, exercising great care in the selection of the standard, and making determinations of the sulphur in each fresh batch of drillings.

General Remarks.—All the methods founded upon Principle A possess one common and serious drawback, viz., the probability of the acid solution, as well as the insoluble residue, containing small quantities of sulphur. It therefore becomes necessary for the operator to test both these, at the expenditure of considerable time and labour, before he can vouch for the accuracy of his results.

With the exception of Parry's and Eggertz's methods the temperature employed has no effect, either injurious or otherwise, upon the accuracy of the results. With Parry's method it must not be sufficiently high to drive over acid fumes, otherwise the colour of the lead acetate solution will be destroyed (this is equally applicable to A II. when the absorbent employed is a solution of lead acetate), while with Eggertz's test a temperature above 40° C. is found to vitiate results.

As far as our experience goes the rate at which the gas is evolved does not appear to influence the results as long as it is caused to pass through a *high column* of the absorbing solution. In employing the oxidation method of Class A I. it is perhaps advisable to allow the gas to pass twice through the oxidising solution.

Principle B.

In this method the sulphur is oxidised into sulphuric acid, with subsequent precipitation as barium sulphate.

The objections brought against this method are that—

(1) Nitrates are precipitated by barium chloride, and that the barium sulphate precipitate would therefore, in all probability, be contaminated with *barium nitrate*. Granted; but if this were the case it would show great carelessness on the part of the operator. This source of inaccuracy may be effectually removed by repeatedly evaporating to dryness the solution containing the sulphuric acid, after the addition of hydrochloric acid. And even supposing it comes down with the barium sulphate, digestion with ammonium acetate will remove it. (2) The results are either too low or too high, according as to whether the solution contains an excess of acid or an amount insufficient to keep the iron in solution. Both these objections are overcome by expelling the excess of acid by evaporation and diluting to a large volume previous to the precipitation of the sulphuric acid, only having sufficient acid present to turn blue litmus-paper decided red. (3) The time required for its performance is considerable. Granted; but we are of opinion that it is better to make a sacrifice of time than of accuracy. When desired the operation may be considerably shortened by neutralising the excess of acid, after the operator has satisfied himself that the whole of the nitric acid is expelled, by the addition of ammonia.

Another objection advanced by those chemists who are antagonistic to the method, is that barium sulphate is soluble (although, we may state, only *slightly* so) in acid solutions of ferric chloride. As it is essential for the satisfactory working of the method that the solution containing the sulphuric acid be decidedly acid, there is, as is obvious, always the danger of an excess being present; their objection, therefore, as far as it goes, is perfectly reasonable and valid.

We have had considerable experience with this method, employing nitric acid as an oxidant, and have always found it to furnish accurate and concordant results.

Conclusion.—We are of opinion that in the hands of an operator who rigidly observes the precautions which are so essential for the successful carrying out, not only of this but any method in which the sulphur is oxidised into sulphuric acid by means of nitric acid, as Principle B, is by far the best and most reliable of all the methods with which we have dealt. And also that all results obtained by the other methods should be checked by it before being finally accepted as correct. Furthermore we are of opinion that Parry's colorimetric method in the hands of a skilful operator yields results which will compare favourably with those obtained by any of the other methods.

The Laboratory, Ebbw Vale,
July 27, 1888.

Transferrers of Oxygen.—Lothar Meyer.—The author examines the power of salts in boiling aqueous solutions to oxidise sulphurous acid. The most powerful action is that of manganous sulphate.—*Zeitschrift*.

ON THE
INFLUENCE OF LIGHT UPON
THE EXPLOSION OF NITROGEN IODIDE.

By J. W. MALLET.

THE statement of L. Gattermann in his recent paper (*Berichte d. Deutsch. Chem. Gesellsch.*, xxi., 751, following up V. Meyer's paper in same vol., 26) on nitrogen chloride, that its explosive decomposition may be brought about, or its susceptibility to explosion much increased, by exposure to bright light, has recalled to my mind the fact, which did not specially impress me at the time, that I myself undoubtedly observed the same relation several years ago in the case of nitrogen iodide.

In a paper on the preparation and composition of the latter substance, published in the first number of the *American Chemical Journal* (April, 1879), it was noted that on two occasions the product obtained with the composition NI_3 or N_2I_6 "exploded in some quantity under water with much violence and complete shattering of the vessel."

I remember distinctly that in one of these cases I had just carried to a window, through which the sun was shining, the beaker full of water at the bottom of which was the black sediment of iodide, and was gently stirring the liquid with a glass rod, holding the beaker up so as to look at it from below, when the rod touched the lower part of the side or the bottom of the vessel, and the explosion occurred.

In the other case the iodide was being washed with ice-cold water of ammonia, the vessel standing on a table exposed at the time to the direct rays of the sun. I do not remember with certainty what seemed to precipitate the explosion on this occasion, but I believe it was the pouring some fresh liquid, from the height of a few inches, on the black sediment of iodide which had just been partially drained by decantation.

Under ordinary circumstances nitrogen iodide, while wet, exhibits no extraordinary sensitiveness, and may be safely worked with, only becoming highly dangerous on drying, so that I have little doubt that bright sunlight was influential in bringing about these two explosions.—*Amer. Chem. Journ.*, Vol. x., No. 4.

THE VOLTAIC BALANCE.

A NEW AND SIMPLE LECTURE EXPERIMENT.

By Dr. G. GORE, F.R.S.

TAKE two small clean glass cups containing distilled water; simultaneously immerse in each a small voltaic couple, composed of either unamalgamated magnesium or zinc with platinum, taking care that the two pieces of each metal are cut from the same piece and are perfectly clean and alike. Oppose the currents of the two couples to each other through a sufficiently sensitive galvanometer, so that they balance each other and the needle does not move. Now dip the end of a slender glass rod into a very weak aqueous solution of chlorine, bromine, iodine, or hydrochloric acid, and then into the water of one of the cups. The voltaic balance is at once upset, as indicated by the movement of the needle, and may be shown to a large audience by means of the usual contrivances.

The chief circumstance to be noticed is the extremely great degree of sensitiveness of the arrangement in certain cases. This is shown by the following instances of the minimum proportions of substance required to upset the balance with an ordinary astatic galvanometer of 100 ohms resistance and with a Thomson's reflecting one of 3040 ohms resistance.

1. *Zinc and Platinum with Iodine.*—With the astatic

galvanometer, between 1 in 3,100,000 and 3,520,970 parts of water.

2. *Zinc and Platinum with Hydrochloric Acid.*—With the astatic galvanometer, between 1 in 9,300,000 and 9,388,185 parts; and with the reflecting one, between 1 in 15,500,000 and 23,250,000 parts.

3. *Magnesium and Platinum with Bromine.*—With the astatic galvanometer, between 1 in 310,000,000 and 344,444,444 parts.

4. *Zinc and Platinum with Chlorine.*—With the astatic galvanometer, between 1 in 1,264,000,000 and 1,300,000,000 parts.

5. *Magnesium and Platinum with Chlorine.*—With the astatic galvanometer, between 1 in 17,000,000,000 and 17,612,000,000 parts; and with the reflecting one, between 1 in 27,062,000,000 and 32,291,000,000 parts of water.

Every different soluble substance requires a different proportion, and with unlike substances the difference of proportion is extremely great. With solutions of neutral salts the proportion of substance required to upset the balance is large; for instance, with chloride of potash, a zinc-platinum couple, and the astatic galvanometer, it lay between 1 part in 221 and 258 parts of water.

The degree of sensitiveness of the balance is usually greater the greater the degree of chemical affinity the dissolved substance has for the positive metal and the less it has for the negative one.

By first bringing the balance with a magnesium-platinum couple and the astatic galvanometer nearly to the upsetting-point, by adding 1 part of chlorine to 17,612 million parts of water, and then increasing the proportion to 1 in 17,000 millions, the influence of the difference, or of 1 part in 500,000 millions, was distinctly detected.

THE MANUFACTURE OF ALUMINIUM:
CASTNER'S PROCESS.

FOR many years the production of aluminium at a low price has hovered before the eyes of metallurgists, but has still eluded their grasp. Steps have indeed been taken by which this metal has been obtained of higher purity and at a reduced cost. We need only refer to the Webster process, now being worked, as we understand, at Solihull, near Birmingham; the electric method devised by the Messrs. Cowles, and which is in actual use on a large scale; and the electric process of Dr. Kleiner, of Zurich, who decomposes the double aluminium and sodium fluoride (cryolite) by an electric current. Still, however, the cost price of the metal has been so high as to prevent not a few of the applications for which it is otherwise well adapted. It is therefore satisfactory to find that a process is being actually introduced at Birmingham by the Aluminium Company, Limited, which—if we make every possible allowance for the eagerness of inventors—will at last put us in possession of cheaper aluminium. The inventor of this new process is Mr. H. Y. Castner, of New York, who has been experimenting upon this important subject for some years. Two years ago he established trial works at Lambeth, and, after further experimentation, he convinced the most experienced metallurgists that he could produce sodium at about one-fifth and aluminium at one-third of their respective former costs. Upon the faith of these results the Aluminium Company was formed, and works were erected at Oldbury, near Birmingham, which came into successful operation about a fortnight ago. On Saturday, July 28th, the process was shown in full operation to a number of scientific and practical gentlemen.

The manufacture resolves itself into four stages:—(1) the production of sodium under the Castner patents; (2) the production of the necessary supply of chlorine by the Weldon process; (3) the manufacture of the double aluminium and sodium chloride by a new process,

invented and patented by Mr. Castner; and (4) the reduction of this double chloride by means of sodium. The first capital improvement is in the production of sodium from caustic soda. The reduction is effected by means of iron carbide in steel retorts, and at the relatively low temperature of 800° , instead of 1500° as in the old process: 1 lb. of sodium is obtained from 6 lbs. caustic soda and 5 lbs. of the iron carbide. The saving in fuel, in wear and tear, and in time is such that, whilst sodium formerly cost 6s. per lb., it is now produced at about 9d. There is no need for us to enlarge on the benefits of cheap sodium, irrespective of the manufacture of aluminium.

As regards the generation of chlorine a very interesting fact is that Messrs. Chance Bros., of Birmingham, the enterprising alkali manufacturers, supply the Aluminium Company with the necessary muriatic acid, and receive in return the crude carbonate of soda, a residue from the production of sodium.

The double aluminium and sodium chloride is formed by passing chlorine gas over a mixture of alumina, salt, and carbon placed in large retorts of a peculiar construction and heated to a high temperature. The chloride formed distils over, and is caught in special condensers. The plant admits of the daily production of 6000 lbs. double chloride, containing about 12 per cent of aluminium, and yielding in practice 10 per cent. Here, again, a considerable economy is effected.

The last stage, the extraction of the aluminium, is effected in furnaces, each of which receives a charge of 80 lbs. of the double chloride, 25 lbs. of sodium, and 30 lbs. of cryolite, which acts as a flux. The charge is heated for two hours to about 1000° , and yields about 8 lbs. of aluminium, the impurities in which do not exceed 2 per cent.

The daily output of sodium is expected to reach 1500 lbs., that of aluminium being 500 lbs. The entire daily production in the world has hitherto been estimated at about 50 lbs.

Before referring to the many possible purposes to which aluminium may be applied, we may venture to glance at an invention by which it is said that this metal may be produced at the cost of a few shillings per pound without the employment either of sodium or an electric current. The uses of aluminium turn on its lower specific gravity, 2.67 (one-fourth that of silver or one-third that of iron); its enormous tensile strength, whether in the pure state or in various alloys; its resistance to the oxidising action of the air, even at comparatively high temperatures, and to the attacks of sulphuretted hydrogen; the beauty of its alloys; and lastly, its sonorous character. Hence, as soon as obtained at a suitable price, it will be the established material for bells, where its lightness will be an additional recommendation for what—on account of their material—are now called "brass" instruments of music, and for pianoforte strings.

Turning to another field, all those parts of balances, telescopes, microscopes, spectrosopes, and other scientific instruments now made of brass, will doubtless be constructed of aluminium.

The question of price has been hitherto the only objection to its use for telegraph-wires. This will be especially the case in the field-telegraphs now employed in military operations. It is evident that a soldier, in laying down such a line, can carry aluminium-wire enough for 3 miles as easily as iron-wire enough for 1 mile, and, in addition, the supports can be lighter and less cumbersome.

Aluminium will also supply "plate" equal in appearance to silver, and not liable to tarnish. An alloy of 1 part of aluminium with about 9 parts of copper rivals gold both in beauty and permanence, and has already come into some use for watch-cases, chains, pencil-cases, and other ornamental articles.

Perhaps in these days of rivalry in the production of warlike appliances one of the greatest outlets for cheap aluminium will be in the manufacture of aluminium

bronzes. Official experiments, here and elsewhere, have shown that castings of these materials possess a tensile strength far in excess of forged iron or steel when made into heavy guns. Such guns henceforth may be cast in any ordinary foundry and finished in the lathe, dispensing with the forging, welding, and shrinking on of rings, the tempering, drilling, and annealing now necessary in the production of the largest guns. Time will be saved, and the service will be supplied with guns at once lighter and more powerful. Mr. Nordenfeldt has discovered, some time back, that castings equal in strength to wrought-iron can be obtained if a little aluminium is incorporated with the fused metal.

All these applications, and others which will readily suggest themselves, only require cheap aluminium to pass at once from the experimental to the practical, industrial stage.

The cost of aluminium is at present from 40s. to 45s. per pound. The Castner process brings the price down to about 15s. This figure may still seem high for many uses; but we must remember that, in consequence of the low specific gravity of aluminium, a given weight of the metal will do the duty of a threefold heavier weight of the ordinary industrial metals. That improvements will be made, further reducing the cost of production, can scarcely be doubted.

DETERMINATION OF SULPHUR IN COKE.

By L. BLUM.

THE author examines the reasons given by different chemists, such as W. Crossley, Grace Calvert, and W. A. Bradbury, to account for the fact that the percentage of sulphur is always found lower by the wet processes than by fusion with alkaline salts. He then analysed ten samples of coke by the potassium chlorate and the bromine and hydrochloric acid method, and obtained results in no case reaching 0.3 per cent. With aqua-regia a percentage of 0.316 was obtained, but the residues on fusion yielded further 0.723 and 0.798 of sulphur. The same samples were then treated by fusion with a mixture of 16 parts sodium chloride, 8 parts potassium nitrate, and 4 parts sodium carbonate, all perfectly dry.

One grm. of the sample was placed in a capacious platinum crucible along with 28 grms. of the saline mixture, thoroughly incorporated, and then ignited. As long as the development of gas in the melt was copious the crucible was heated only to low redness (at the front of the muffle). When the chief action was over a stronger heat was applied until the melt was in a tranquil flux. The melt when cold separates readily from the crucible. It is dissolved in water acidulated with hydrochloric acid. After a further addition of strong hydrochloric acid (in order to decompose any existing nitro-compounds) it is evaporated to dryness, taken up again in hydrochloric acid and water, the silica which separates is filtered off, and the sulphuric acid is determined gravimetrically in the filtrate by means of barium chloride. All the samples treated in this manner gave percentages of sulphur ranging from 0.907 to 1.147.

These results prove the utter uselessness of all the wet methods.

The author agrees with F. Muck that, in addition to the sulphur present as calcium and iron sulphide, there is a compound present derived from the organic sulphur of the coal. The sulphur of the sulphides is dissolved by acids and oxidising agents, but the organic sulphur resists such agents.

Herr Blum suggests that in future it may be required to determine separately the proportion of sulphur existing in each of these two states. This may be effected by first determining total sulphur as above, and then estimating the portion combined with Ca or Fe by means of

the potassium chlorate, the bromine and hydrochloric acid, or the aqua-regia method.—(Separate Reprint from the *Zeitschrift für Analytische Chemie*.)

THE CLASSIFICATION AND NOMENCLATURE OF METALLINE MINERALS.*

By T. STERRY HUNT.

1. The writer in April, 1885, presented to the National Academy of Sciences the project of A Natural System in Mineralogy, which was farther elaborated in an essay before the Royal Society of Canada in May of the same year, published in Volume III. of the *Transactions* of that Society, and with revisions and additions in his "Mineral Physiology and Physiography" in 1886 (pp. 279—401). In† this essay it was maintained that such a system cannot be established on the sensible characters of the species alone, as taught by the school of Mohs, nor yet on chemical composition and relations to the neglect of such characters, in accordance with the views of the Berzelian school or of those who propose a chemico-crystallographic scheme like that of Groth. It was the aim of the writer to show that the hardness, the specific gravity, and, moreover, the greater or less susceptibility to chemical change in species are intimately related to chemical constitution; and that a natural system of classification which, in the words of John Ray, "neither brings together dissimilar things nor separates those which are nearly allied," must take into account all these various characters and relations, alike dynamical and chemical. The error of attaching an undue importance to a single subordinate character is illustrated in the case of crystalline form, which may vary, while specific gravity, hardness, colour, lustre, and chemical composition all alike remain unchanged, as seen, for example, in the native sulphides of zinc and of silver.

In pursuance of these ideas the whole inorganic kingdom was declared to belong to Mineralogy, although as a branch of Natural History it is generally confined to native species. The real position of mineralogy, as distinguished under its various heads of Systematic, Descriptive, and Physiological Mineralogy, is set forth in the following tabular view of the natural sciences, copied with slight revision from the volume just cited.

2. The classification then proposed by the writer divides the mineral kingdom into four classes, namely: I., *Metalline*; II., *Oxidised*; III., *Haloid*; and IV., *Pyri-*

caustate (combustible or fire-making) species. These again are divided into orders, and in some cases into sub-orders, as was set forth on page 382 of the already cited volume. In the large and important order of the SILICATES, the only one then considered in detail, there was recognised in each one of its three sub orders of Proto-silicates, Proto-persilicates, and Persilicates—five tribes, designated Hydrospathoid, Spathoid, Adamantoid, Phylloid, and Colloid (or Porodic); called in some cases by other more distinctive synonyms as Pectolitoïd, Zeolitoïd, Ophitoïd, and Argilloïd; in farther extension of which, we may say, Amphiboloid, Feldspathoid, Granatoid, Topazoid, Talcoïd, Micoid, &c., for the other tribes. The characteristic species of these tribes were then critically examined as regards chemical composition and the relations of this to specific gravity and to hardness. These relations were shown in separate tables for the various tribes, and farther in three synoptical tables of the sub-order (*loc. cit.*, pp. 399—401). The order of the OXYDATES (included, like the last, in the class of the OXYDACEÆ) was at the same time more briefly considered, and shown to include representatives of five similar tribes (p. 376). In various orders of the same class, such as CARBONATES and BORATES, as likewise in the sub-orders of the HALOID-ACEÆ, such as CHLORIDES, the soluble and sapid species were recognised as forming tribes—Carbo-salinoid, Boro-salinoid, and Chloro-salinoid—contrary to the teaching of Mohs and his followers, who made these characters the basis of a class-distinction. It should be added that the species of all these various tribes have farther to be arranged in genera, and to complete the system require a binomial Latin nomenclature.

3. In the study of the various species of the order of Silicates, notice was in every case taken not only of the specific gravity of the species, but of the relations between this and its equivalent or so-called molecular weight, as shown in what is generally known as its atomic volume, calculated by the formula $p \div d = v$. For the purpose of thus comparing related species it was necessary to fix a simple unit for p . As we have since said in the study of the species of Classes II and III.: "We assume as the unit for p a weight including that of $H = 1.0$, of $Cl = 35.5$, or of $O \div 2 = 8.0$. By thus adopting a combining weight of 8.0 for oxygen as a basis, we get a unit which gives a common term of comparison for oxides, sulphides, chlorides, fluorides, and for intermediate compounds like the oxysulphides and oxyfluorides common in native species. It is, of course, a hypothetical unit which, for elemental species and for fluorides, chlorides, &c., corresponds with the normal vapourous species; but for oxidised species is some fraction thereof, as in the cases of water-vapour, H_2O , of spinels, and other oxides.

* Read before the American Philosophical Society, May 4, 1888.

"We may readily extend this system of hypothetical units from silicates to carbonates, sulphates, phosphates, and more complex species by dividing in all cases the empirical equivalent weight by twice the number of oxygen portions ($O=16\cdot0$), plus the number of chlorine or fluorine portions. We have for example:—

		$\bar{p}$.
Forsterite . . .	$\text{SiMg}_2\text{O}_4=140\div8$	17.50
Calcite . . .	$\text{CCaO}_3=100\div6$	16.66
Karstenite . . .	$\text{SCaO}_4=136\div8$	17.00
Gypsum . . .	$\text{SCaO}_4\cdot2(\text{H}_2\text{O})=172\div12$	14.33
Apatite . . .	$3(\text{P}_2\text{Ca}_3\text{O}_8)\cdot\text{CaF}_2=908\div50$	18.16

"In the writer's late essay on "A Natural System in Mineralogy," the values of $\bar{p}$ have been thus determined. These silicates are there represented by a new notation which employs symbols in small letters to represent quantivalent ratios; the combining weights of the elements being divided by their valency, and in all cases followed by their coefficients. The formula of forsterite thus becomes $(\text{mg}_1\text{si}_1)_2$, that of orthoclase, $(\text{k}_1\text{al}_3\text{si}_{12})\text{o}_{16}$, and that of topaz, $(\text{al}_3\text{si}_2)_4\text{o}_{4f}$.

"While a similar unit is equally applicable to all haloid species, it has been found more convenient for the metalline species which constitute Class I., including unoxidised metals and their compounds with one another, and with arsenic, antimony, sulphur, selenium, and tellurium, to divide the formula by the sum of the valencies therein represented; so that for all such species the unit $\bar{p}$ gives not the mean integral weight of an oxygen compound in which $O=8$, but that of the element corresponding to $S=16$, to $\text{Fe}=28$, to $\text{Ag}=108$, to $\text{As}=25$, $\text{Sb}=40$, and $\text{Bi}=69.3$,"* represented respectively by s_1 , fe_1 , ag_1 , as_1 , sb_1 , and bi_1 .

4. The law of condensation and of expansion by volumes, familiarly known in the chemistry of gases and vapours at ordinary pressures, is, as the writer has endeavoured to show, still further exemplified in the case of the very dense vapours into which, under much greater pressures, liquids like water, alcohol, hydrocarbons, and, theoretically, all chemically stable liquids, pass when heated sufficiently; that is to say above their so-called critical points, when they necessarily assume the vaporous condition. The conversion of all gases and vapours by reduction of temperature and augmentation of pressure into liquid and solid forms, helps us to understand that the same laws of combination by weight, and of condensation or integration of volume, apply alike to gases and vapours on the one hand, and to liquids and solids on the other. The relation of condensation (represented by specific gravity) to equivalent weight, which thus becomes a fact of fundamental importance, is shown by comparing the quotient got by dividing the received equivalent (so-called atomic or molecular) weight by the specific gravity of the body as determined for all liquid and solid species, taking water as unity, as in the formula $\bar{p}\div d=v$. The equivalent weight $\bar{p}$ is, as we have seen, that deduced from the empirical chemical formula calculated from hydrogen as unity.

Thus hydrogen being $1=\text{H}$, the equivalent weight of carbon dioxide, whether as gas, liquid or solid, is assumed as $44=\text{CO}_2$; that of water, in any of its states, is taken as 18 (or, more exactly, 17.96) $=\text{H}_2\text{O}$, and that of the various forms of silica as $60=\text{SiO}_2$; while that of carbonate of lime, whether as calcite or aragonite, is $100=\text{CCaO}_3$. These weights in the case of gaseous bodies are really the weights of equal volumes, compared with that of hydrogen at the same temperature and pressure, and are truly equivalent weights. The law of condensation, however, shows us that, in the case of liquid and solid species, we have to deal with much more complex formulæ than these. In fact, the minimum equivalent weights deduced from analyses of the chlorides of the

ammonio-cobalt bases give numbers of 500 and upwards, and, in the case of a certain metaphosphate, equal 2540. The complex potassio-cobaltic nitrite is represented by a formula giving an equivalent weight of not less than 958. These weights are surpassed by those deduced for the complex silico-tungstates and phospho-tungstates, our knowledge of which has been much extended by the late researches of Wolcott Gibbs on what he has called "the complex inorganic acids." Therein he has made known the existence of progressive or homologous series, the successive terms of which differ by 2WO_3 , and rise from 4WO_3 to 24WO_3 , and even 60WO_3 ; having formulæ from which the minimum molecular weights deduced are represented by many thousands, $\text{H}=1$. Thus the golden insoluble crystalline compound of tungsten, oxygen, and sodium, described by Wöhler, is probably, according to Gibbs, $16\text{WO}_3\cdot4\text{WO}_3\cdot7\text{Na}_2\text{O}=5,002$, while to another crystalline species, soluble in water and hydrous, he ascribes the formula,—

This, according to him, has "the highest molecular weight yet observed." The studies of Gibbs and of many others whose work in this field has been briefly summarised by the writer ("Mineral Physiology," pp. 386—389), unite in showing that a great complexity of composition may exist in definite crystalline compounds, and moreover, that very small portions of different substances may not only occur as necessary elements in such a compound, but may even change essentially its chemical relations. Thus, in a complex tungstate containing $12\text{WO}_3=2784$, the addition of $\text{SiO}_2=60$ suffices to determine the production of a new type with changed basicity. In like manner the addition to a compound, containing $24\text{WO}_3=5568$, of $\text{P}_2\text{O}_5=142$, gives a new and distinct acid type. Moreover, oxygen in these bodies may be in part replaced by fluorine; while platinum, selenium, tellurium, and many other elements may enter in small but definite amounts into the polytungstates and polymolybdates, as well as organic radicals, such as methyl, ethyl, and phenyl. These remarkable results are regarded by Gibbs as forming "a new department of inorganic chemistry." In commenting upon them, however, it has been elsewhere said:—

"It will be remembered that I had already, in 1853, proclaimed that the whole chemistry of solids and liquids is only intelligible when regarded as a history of just such complex inorganic acids and salts; that the distinction between organic and inorganic chemistry is no longer tenable; that the same principles of homology and polymerism are applicable alike to the bodies of the carbon series and the silicon series; that the native crystalline carbonates, or carbon-spars, are polycarbonates, with equivalent weights of not less than from 1500 to 2500; that the pyroxenes, feldspars, and tourmalines are polysilicates of equally complex constitution, and are represented by formulæ which show the existence among them both of polymers, probably homologous, and of anisomeric homologues. These conceptions, all of which were explicitly set forth and defended in 1852 and 1853, underlie the writer's philosophy of the mineral kingdom, as then enunciated, and as persistently maintained to the present date."*

5. It was not, however, till a much later date that a farther attempt was made to fix the *integral weight*, as I have designated the so-called molecular weight of solid species. By extending to such species the law of equivalent volumes, the conclusion was reached that their integral weights were even far greater than had been suspected by the writer in 1853. In fact, that of water itself, the unit of specific gravity for liquids and solids, being, in round numbers, 21,400,† the weights for these

* "A New Basis for Chemistry," 2nd Edition, § 139; also the author on "Chemical Integration," *American Journal of Science*, August, 1887.

* "A New Basis for Chemistry," 1887, § 27.

† In liquid water 192 volumes of water-vapour at standard temperature and pressure are condensed into a single volume, which, if $\text{H}_2\text{O}=17.96$, gives an integral weight of 21,408; but in view of the

various species must be as much greater as their specific gravities are higher than this unit. We thus find that the solid forms of carbon dioxide and silicon dioxide, of carbonate of lime, and even of the ammonia-cobalt salts, and the highest members of the polytungstate series, represent in all cases polymeric or condensed derivatives of the normal species, which is, for the most part, unknown, or appears, as in the case of CO_2 and H_2O , in a gaseous form. A species like calcite, of sp. gr. 2.729, is represented by 584CCaO_3 or by $\text{C}_{584}\text{Ca}_{584}\text{O}_{1752} = 58,400$. In like manner other mineral species must be represented by formulæ more complex and weights far higher than those deduced by Gibbs for his polytungstates. In the case of such compounds, partial substitutions, and small additions, affecting but slightly the centesimal composition of a species, may nevertheless be essential to its chemical constitution, as shown by Gibbs in the cases of silicic and phosphoric oxides added to the polytungstates. In the formula above assigned to calcite, with Ca_{584} , the substitution of Mg_{10} would introduce into the species only 0.72 of magnesia. Such substitutions and small additions would, however, if found in ordinary analyses of mineral species, be disregarded as impurities not essential to the composition. In like manner the small amounts of fluorine, of chlorine, of hydrogen, of boron, and of phosphorus, so often met with in native silicates, are not to be looked on as accidental ingredients, but as essential parts of highly complex integers. Farther and more critical chemical analyses are necessary before we can fully know the constitution of dense insoluble species, and the great difficulty is to decide how far these small portions of elements are due to impurities, and how far they are elements necessary to the constitution of the species, questions which in many cases can only be solved by much care and study.

6. The non-oxidised metalline minerals, embracing the metals, their alloys, and all their compounds with sulphur, selenium, tellurium, phosphorus, arsenic, antimony, and bismuth, are, in the natural-historical classification of Mohs and his followers, comprised in four orders:—Pyrites, Metals, Glances, and Blendes (Pyrites, Metalli, Lamprite, and Minia of Breithaupt). All of these we have included in Class I., METALLACEÆ, embracing but a single order, METALLATA, which is, however, divided into two sub-orders. The reasons for including the metals and their various alloys in the same order with sulphides, selenides, tellurides, phosphides, arsenides, antimonides, bismuthides, sulpharsenides, sulphantimonides, &c., are two-fold; first, the resemblances between the typical and malleable metals, such as gold, silver, lead, copper, nickel, and iron, and the elementary metalline species, tellurium, arsenic, antimony, and bismuth, are such that the compounds of these with the metals above named cannot well be separated from alloys. Another reason is to be found in the complex nature of many artificial products known to us as metals. Thus, the cast-irons from the blast-furnace are compounds, apparently homogeneous, of iron with small quantities of sulphur or of phosphorus with silicon and with carbon, while copper may, in like manner, contain small quantities of phosphorus, of arsenic, or of silicon. These constitute sulphides, phosphides, arsenides, silicides, and carbides of iron and of copper, in which the amounts of the added elements, though proportionally small, nevertheless modify profoundly the character of the compounds, affording additional illustrations of the principle insisted upon above in speaking of oxidised species.

7. The division of the Metallata into two sub-orders,

uncertainty still prevailing as to the precise weight of oxygen, hydrogen being unity, the number 21,400 is adopted as a close approximation. In former publications by the writer, by an error in calculation, instead of $1192\text{H}_2\text{O}$ the formula of water has been given as $1628\text{H}_2\text{O}$, which, with $\text{H}_2\text{O} = 17.9633$, gave an integral weight of 29,244. This mistake was corrected in a note on "The Integral Weight of Water," in the *L. E. and D. Philos. Magazine* for April, and in the *American Journal of Science* for May, 1888. See also the author's "New Basis for Chemistry," 2nd Edition, *passim*.

which we have designated Metallometallinea and Spato-metallinea, is based upon the radical differences which distinguish the great groups of the Glances and the Blendes. The first suborder, like the Glances, includes alike simple sulphides like galena, argentite, chalcocite, metacinnabar, stibnite, and molybdenite; selenides like eucairite and clausenthalite; tellurides like altaite, sylvanite, and tetradymite; sulpharsenides like enargite; sulphantimonides like bournonite and stephanites; ulphobismuthides like emplectite and kobellite. To the Metallometallinea also belongs the order Pyrites of Mohs. This not only includes the harder simple sulphides, as marcasite, pyrite, siegenite, and laurite, and as pyrrhotite, chalcopyrite, and millerite; but arsenides such as smaltite, leucopyrite, and niccolite; antimonides like breithauptite, harsfordite, and dyscrasite; sulpharsenides like arsenopyrite and cobaltite; sulphantimonides like ullmannite; and sulphobismuthides like grunauite. In this same sub-order, for reasons already given, belong the metals and alloys, including metallic arsenic, antimony, and bismuth, and also the metallic forms of selenium and of phosphorus.

In the second sub-order the metals are not represented by any known species, but by the non-metallic forms of selenium and phosphorus, and by the various modifications of sulphur. This sub-order includes, moreover, simple sulphides like sphalerite, wurtzite, greenockite, hauerite, oldhamite, cinnabar, and realgar; sulpharsenides like proustite and tennantite; and sulphantimonides like pyrrargyrite and miargyrite. The opacity and lustre of the compound species of the first sub-order, and their occasionally seftile character, connect them closely with the typical metals. On the other hand, the transparency, the absence of metallic lustre and aspect from the species of the second sub-order recall the physical characters of oxides like zincite, cuprite, and senarmontite, with which they are connected through the oxy-sulphides, voltzite and kermesite. It is to recall these resemblances to the sparry Oxidates that we have called this sub-order Spato-metallinea. It is worthy of note that not only the elements selenium and phosphorus, but the sulphides of mercury and of antimony, are found in two distinct specific forms, and belong to both of these sub-orders; and there seems some reason to believe that under the head of fahlerz, or gray copper, may be included, besides the species belonging to the Spato-metallinea, others which pertain to the Metallometallinea.

7. In proceeding to divide into tribes and genera the various groups of species indicated in the preceding review of the order of Metallata, we are guided alike by the composition, as shown by chemical analysis, and by the physical characters of hardness and condensation. The latter, as indicated by the value of v , calculated for the elemental unit as already defined (§ 3), is the reciprocal of the coefficient of condensation. This value will be seen to diminish with the increase of hardness of the species, as represented by degrees given on the scale of Mohs, in which the hardness = $H = 1.0 \dots 10.0$.

(To be continued).

A DETERMINATION OF THE RELATION OF THE ATOMIC WEIGHTS OF COPPER AND SILVER.*

By THEODORE WILLIAM RICHARDS.

IN the Report of the Committee on Electrolysis made to the British Association at Birmingham, of which an advance copy has been received by Professor Cooke through the kindness of Dr. Oliver Lodge, a direct determination is given of the ratio between the atomic weight of copper

* Contributions from the Chemical Laboratory of Harvard College. From the *Proceedings of the American Academy of Arts and Sciences*, vol. xxiii

and that of silver, based on the electrolytic experiments of W. N. Shaw. As the value of the ratio thus obtained is quite different from that usually accepted, it seemed to Professor Cooke desirable that the results should be confirmed by a direct chemical method, and the writer was intrusted with this investigation.

Of the work worthy of consideration which has thus far been done upon the atomic weight of copper, first in chronological order comes that of Berzelius,* who made two determinations of the weight of copper formed by the reduction of pure cupric oxide by hydrogen. He found the percentage of copper in this compound to be 79.823 ± 0.002 . This corresponds to an atomic weight of 63.153 , taking oxygen = 15.963 , with Clarke. The next determination was by Erdmann and Marchand,† who used the same method. They found the percentage of copper in cupric oxide to be 79.845 ± 0.0038 as a mean of four determinations,—a value which makes $\text{Cu} = 63.316$. Millon and Commaille,‡ in three determinations,—which did not, however, closely agree with one another,—found the relation, $\text{CuO} : \text{Cu} = 100 : 79.7787$; and calculating from this relation the atomic weight of copper, the value 62.979 is obtained. Dumas§ made several determinations of the reduction of cupric oxide and the synthesis of cuprous sulphide, and calculates the value $\text{Cu} = 63.5$.

Hampe,|| whose work gave the most concordant results thus far secured, obtained from three determinations of the percentage of copper in cupric oxide the mean value of 79.8347 ± 0.0013 , and from two analyses of anhydrous cupric sulphate by electrolytic precipitation he found the proportion $\text{CuSO}_4 : \text{Cu} = 100 : 39.725 \pm 0.0007$. The atomic weights of copper from these two methods are respectively 63.197 and 63.173 .

This was in 1874; and the subject has rested undisturbed until last year, when W. N. Shaw, in the paper before referred to, sought to prove the accuracy of Faraday's law of electrolysis in atomic proportions, by means of the actual weights of silver and copper deposited in cells in the same circuit. For the particulars of his method the Report of the Committee on Electrolysis should be consulted; it is sufficient here to say that as the mean of many determinations he finds the ratio of the silver and copper precipitated to be $3.39983 : 1$. Correcting this result for variations in current density, he obtains the value 3.39888 , and finally adopts the practically identical value 3.400 , which makes the ratio $\text{Ag} : \text{Cu} = 17 : 10$. This last value makes $\text{Cu} = 63.333$, while the corrected value gives as the atomic weight the quantity 63.360 .

Below is a summary of all the results:—

Berzelius, from CuO		63.153
Erdmann and Marchand, from CuO		63.316
Millon and Commaille, from CuO		62.979
Dumas, from CuO and Cu_2S		63.5
Hampe, from CuO		63.197
„ from CuSO_4		63.173
W. N. Shaw, by relation to silver		63.333
„ „ „ corrected		63.360

The most obvious chemical method for the determination of the relation of the atomic weights of silver and copper is by the precipitation of silver from a solution of a pure silver salt by means of pure copper; and this was the method adopted in the present determination. Hampe, in his work on the atomic weight of copper, attempted the same method, but rejected it for two reasons,—the first being that the silver dissolved, or appeared to dissolve, to a slight extent in the hot water used for washing; and the second being that it was impossible to prevent copper from coming down with the silver, no matter how long the precipitate was digested with the

argentic nitrate solution. As will be seen, however, both of these difficulties have been entirely overcome.

The silver salt selected for the precipitation was the nitrate, on account of its ready crystallisation, its easy solubility in water, and the facility with which it can be obtained pure. For the preparation of the salt used in the work, ordinary pure argentic nitrate was crystallised many times from hot water, and finally fused for two hours in an air-bath kept at 205°C .—a few degrees above its melting-point. This preparation was a white translucent substance interspersed with transparent crystals, dissolving completely in water, and giving a colourless solution which was wholly neutral.

The copper used was prepared by electrolysis from cupric sulphate, through the kindness of Mr. Wilson, of the University Press. It was cut into small pieces, and these were digested in succession with weak potassic hydrate, dilute sulphuric acid, and then a very large amount of water. The copper was then boiled with water for about half an hour and washed with a large amount of distilled water, then dried and reduced at a low red heat by means of perfectly pure hydrogen, and allowed to cool in a stream of the gas. The metal thus prepared had a beautiful red metallic lustre, and showed no trace of oxidation after keeping a month. Before use it was dried in an air-bath at 110° , allowed to cool in a desiccator, and weighed by itself on a balance which was distinctly sensible to a twentieth of a milligramme. In addition to receiving the treatment described above, the copper used in the fifth and sixth experiments was oxidised in a stream of pure air for half an hour, and then again reduced by hydrogen; but the concordance of those two results with the others shows that this precaution was not necessary.

In a few preliminary experiments it was found that on the temperature of the solution, and on the temperature alone, depended the regularity with which the silver was precipitated by the copper. At 90° the deposition is very rapid, nitrous fumes are evolved, and a large amount of copper comes down with the silver. As the temperature of the solutions used is lower, the reaction becomes less rapid, and the amount of copper deposited with the silver less, until at ordinary temperatures it is comparatively small; and below 0° the silver comes down absolutely pure, and not the least evolution of gas is observed. One of the difficulties of Hampe can then be overcome by keeping the beaker containing the solution in a freezing mixture; and the perfect definiteness of the reaction, which before might have been questioned, is thus established. The duration of the reaction at -1° is from twelve to twenty-four hours, according to the dilution of the argentic nitrate. The more dilute the solution is, the longer the precipitation takes, and the more finely divided is the deposited silver; but when the solution is very concentrated the reaction is completed in a comparatively short time, and the silver comes down in a beautiful compact crystalline crust, which takes the form of the copper.

The silver which was formed was collected in a Gooch crucible and washed with cold water, of which less than 250 c.c. were necessary to give a filtrate in which no trace of silver or copper could be detected.

The fact that the determinations given below agree so exactly with each other is of itself proof that no silver was dissolved,—first, because the precipitate in the different experiments was of very different degrees of fineness; and secondly, because the precipitate in each experiment was washed with a different amount of water, the silver of the last experiment having at least four times as much water passed over it as that of the first. And the fact that the results are not affected by either circumstance shows clearly that no perceptible amount of silver could have been dissolved; for if so, the loss must have varied both with the condition of the precipitate and with the amount of the wash-water. The different result obtained by Hampe was probably the effect of hot water on a very finely divided precipitate.

Relation of Silver to Copper.

No. of Expt.	C.c. H ₂ O used.	Weight Cu taken.	Weight Ag formed.	Equivalent.	Atomic weight Cu.	
				Ag ₂ : Cu = 1: n.	Ag = 108.	Ag = 107.675.
1.	20	0.53875	1.8292	0.29452	63.618	63.427
2.	25	0.56190	1.9076	0.29456	63.624	63.432
3.	120	1.00220	3.4016	0.29462	63.639	63.447
4.	30	1.30135	4.4173	0.29462	63.638	63.447
5.	20	0.99870	3.39035	0.29457	63.628	63.437
6.	25	1.02050	3.4646	0.29456	63.623	63.434
Average				0.29457	63.628	63.437

The silver, whether in crystalline plates or in crystalline powder, formed a very convenient precipitate with which to work; it was easily transferred and easily washed, did not adhere to the glass, and was in every way adapted for quantitative work.

The conditions of the following experiments as regards the quantity of water and the excess of argentic nitrate used above the amount required to dissolve the copper, were varied as much as possible. In some determinations barely enough of the argentic nitrate was used to effect the solution, while in others the excess of the silver salt amounted to nearly 2 grms. The time allowed the reactions was also varied from twenty-four to seventy-two hours.

The mean value, 63.437, has a greatest variation of ± 0.001 , and a probable error of ± 0.0023 .

The value obtained by Shaw was 63.333

" " " " corrected.. 63.360

The value given by Clarke is.. .. 63.173

It remains only to prove the absolute purity of the copper used and the silver formed. The only metals which could affect the atomic weight of copper to an appreciable extent, if present in traces, are bismuth and silver. The former was tested for with great care, using a delicate spectroscope, and not the faintest trace of the very well-defined blue bismuth line was apparent; further, ten grms. of the copper were dissolved in nitric acid, a little potassic hydrate added to the diluted solution, and the whole boiled and shaken for three hours. According to Hampe, all the bismuth present will be found in the basic precipitate; this was tested qualitatively for the metal, and not a trace was found. The solution of a portion of the copper in pure nitric acid gave not the faintest trace of opalescence with hydrobromic acid, excess of ammoniac hydrate, or baric chloride. A gm. of the copper was tested for arsenic and antimony in a Marsh-Berzelius apparatus, and no trace of a mirror was obtained. As the presence of so much copper would cause the generator to run too rapidly, the solution was treated with just enough potassic ferrocyanide to effect precipitation, and the colourless filtrate was run into the apparatus. This method has been found to give good results. The copper and the precipitated silver each dissolves in nitric acid without leaving a trace of residue.

If the copper is pure, the only possible impurity which the silver could contain is copper, and this was tested for with great care in each precipitate by dissolving one to two grms. in nitric acid and adding excess of ammoniac hydrate. In no case was the slightest blue colour noticed, and as under the same circumstances the tenth of a milligram of copper gave a distinct bluish tinge it may be assumed that the silver contained no copper. This method is a convenient one for the preparation of chemically pure silver, and avoids the necessity of fusion and the concomitant absorption of oxygen and possible admixture of silicic anhydride.

Although the value of the atomic weight of copper obtained, 63.44, does not exactly coincide with Shaw's results, it is at least very much nearer to them than is the old accepted value of 63.17; especially if we take his result as corrected for current density. The new value is

very nearly that found by Dumas from cuprous sulphide, and it falls within the limits assigned by L. Meyer and Seubert as the possible error of the accepted value.

OBITUARY.

JULES HENRI DEBRAY.

WE much regret having to put on record the unexpected death of the distinguished chemist Jules Henri Debray, which took place on July 19th. The deceased was the pupil, assistant, and intimate friend of the late illustrious Sainte-Claire Deville, and became his successor, both officially and in the development of his ideas on dissociation. The activity of the late *savant* was incessant and manifold. He was a Member of the Academy of Sciences, Professor at the Paris Faculty of Sciences, "Maitre de Conférences" at the Higher Normal School, Assayer to the "Garantie" of Paris, Vice-President of the Society of Encouragement for National Industry, Member of the Higher Council of Public Instruction and of the Consulting Committee of Arts and Manufacture. He had reached the age of sixty, but was in the enjoyment of full health and vigour.

CORRESPONDENCE.

ESTIMATION OF SULPHUR IN IRON AND STEEL.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS (vol. lviii., p. 59) there appears a letter from Mr. J. Jas. Morgan, in which he disputes a statement made by the authors that a colorimetric method for the estimation of sulphur in steel (devised by Mr. Parry and published by Mr. Morgan in the CHEMICAL NEWS, vol. lvi., p. 13), does not admit of accurate comparison with the standards, owing to a portion of the PbS formed precipitating. In his quotation are substituted for an illustrative percentage, 0.05, the figures 0.03. The authors can only reiterate their experience of the method.

Mr. Morgan states under three heads the causes which, in his opinion, led to the failure of the authors to obtain accurate results. We repeat our statement that the process was carried out under the "prescribed conditions." The solutions were not hot, nor even warm. The comparisons were made at once. The acetate solution was of the exact strength recommended by Mr. Morgan. In their own method the authors specify cold solutions and rapid comparison, whereas Mr. Morgan laid no stress on these points in the article which he published. If it is claimed that the latter will distinguish a steel containing 0.025 from one containing 0.05 per cent, the authors do

not dispute for a moment that such is the case, but a nearer approximation than this cannot be relied upon,* whereas the authors' method gives results much nearer the truth.

Messrs. Parry and Morgan evolve a small volume of H_2S into a flask without any attempt to remove the air, and the oxygen in the latter is thus in contact with the H_2S both in the flask and during its passage through the acetate solution, under which conditions the danger of a variable decomposition of the H_2S is obvious.

The cause of the precipitation is the motion communicated to the liquid by the passage of the evolved gases. In addition to particles of PbS suspended in the liquid, the end of the inlet tube and the surface of the Nessler tube at the point of contact of the liquid with the air are always coated with PbS .

The authors agree with the statement that the principle involved in both methods is the converse of that used for the estimation of lead in water; but in the method described by Mr. Morgan the conditions necessary to obtain reliable results are departed from. In the authors' process these conditions are strictly adhered to. Few chemists would attempt to determine the lead in water by producing the colour with a stream of H_2S gas. A small volume (2 c.c.) of a strong solution is invariably used by experienced water analysts.

However, the approximate colorimetric method detailed by the authors was of very secondary importance compared with their volumetric process headed "Method II." This method, without loss of accuracy, yields in two hours a result hitherto occupying two days to obtain.—We are, &c.,

Sheffield, August 7, 1888.

ESTIMATION OF TANNIN.

To the Editor of the Chemical News.

SIR,—In the estimation of tannin in barks and bark extracts by the "gelatin process" is it not possible that erroneous results may be obtained by the presence of iron in the solution? I find that if potash alum be added to a watery solution of gelatin and then ferric chloride added, that a gelatinous brown precipitate is formed, and that the solution has no colour, but is quite clear, thus showing that no iron is in the supernatant liquid. What is this precipitate and what is it caused by?—I am, &c.,

"YOUNG ANALYST."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of emperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 4, July 23, 1888.

Remarks on the Determination of Nitrogen in Vegetable Soils.—M. Berthelot and G. André.—The authors conclude that in a soil poor in nitrates the determination of nitrogen by means of soda-lime may be executed at once with safety.

Analysis of the Water of the Nile.—A. Muntz.—This analysis refers merely to the proportion of nitrogen present as nitrate, which is not high. The greatest quantity found was 4.09 m.grms. nitric acid per litre,

* It is not, however, possible to distinguish with certainty a steel containing 0.10 from one containing 0.125 per cent.

corresponding to 7.62 m.grms. potassium nitrate, a quantity which falls short of the values found for other rivers. Boussingault has found 11 m.grms. potassium nitrate per litre of Seine water. It does not, therefore, seem that the nitrates contained in the water of the Nile can be regarded as the principal cause of the fertility of Egypt. Its power of producing a succession of abundant harvests must be sought in the deposits of mud.

Researches on Some Salts of Rhodium.—E. Leidié.—The author describes the double ammonium-rhodium chloronitrate, rhodium sesquisulphate, and the double rhodium-potassium, rhodium-sodium, rhodium-ammonium, and rhodium-barium oxalates.

A New Method of Determining Lithium by Means of Fluorides.—A. Carnot.—The spectroscopic gives valuable indications for the qualitative detection of lithia, but a comparison of the intensity of the spectral rays gives merely a doubtful approximation as to the proportion of the metal, especially if more than a few m.grms. per litre are present. The reagent used is ammonium fluoride. As the commercial salt is often contaminated with fluosilicate it is purified as follows:—Some grms. of the salt are dissolved in a small volume of water, a double volume of ammonia is added, the whole is boiled for a few seconds, let cool, filtered, and washed with ammonia. The silica is thus eliminated and we have the fluoride in a strong ammoniacal solution, which is preserved in a covered platinum crucible. If we have in solution a few decigrams. at most of a salt of lithium with quantities of other alkaline salts not more than ten or fifteen times greater, we operate as follows:—The solution is reduced to a few c.c. in a tared platinum capsule; ammonium fluoride and an excess of ammonia are added up to a volume of 15 to 20 c.c. The whole is well mixed and let settle, when there is formed a white gelatinous precipitate, scarcely visible, of lithium fluoride, which partly adheres to the bottom of the capsule. The next day it is complete, when we decant almost all the liquid upon a very small filter and pour in its place a few c.c. of ammoniacal water and ammonium fluoride, stir up with a platinum spatula and let settle. Soon afterwards we make a second and a third decantation and wash the filter with a few drops of the same reagent. Thus we remove all the soluble alkaline salts, and we have, partly on the filter and partly in the capsule, all the lithium salt imbued merely with ammonia and ammonium fluoride. The volatile matter is expelled at a very gentle heat, the filter is burnt, the ash treated with a few drops of dilute sulphuric acid, and all the liquid is collected in the tared capsule. It is evaporated and ignited gently until all acid vapours have completely disappeared and the residue is weighed as neutral lithium sulphate. To take account of the solubility of lithium fluoride in the ammoniacal liquid its total volume is measured, ranging from 30 to 50 c.c. According to former results, and remembering that the washing waters remained in contact with the precipitate for a short time only, we may admit that 10 c.c. of the liquid contains approximately 2 m.grms. lithium fluoride = 4 m.grms. sulphate or 1 m.grm. lithia. The quantity thus calculated is added to that weighed directly.

Certain Hydrates of Potassium Ferrite Crystallised in the Dry Way.—G. Rousseau and J. Bernheim.—The authors establish the existence of three successive hydrates, characterised by their different dissociation-tensions.

Determination of Glycerin by Oxidation.—V. Planchon.—The author notices the extreme ease with which this substance is completely burnt by potassium permanganate in an acid solution, being converted into water and carbon dioxide according to the equation—

He mixes 100 c.c. of a solution containing 0.5 gm. glycerin with 4.2 grms. of powdered permanganate, and 100 c.c. of water containing 15 grms. sulphuric acid. On

heating gently, carbonic acid begins to escape about 40°. At higher temperatures the escape is more abundant, and at 100° the total carbonic acid is eliminated.

On Yttrium and Sodium Chloride, Bromide, and Sulphide.—A. Dubois.—A study, chemical and optical, of anhydrous crystalline yttrium chloride, of the corresponding bromide, and the crystalline double yttrium and sodium sulphide.

On Anagyrene.—E. Hardy and N. Gallois.—Anagyrene is the active principle of *Anagyris foetida*, a poisonous plant growing in Algeria. Anagyrene is an amorphous yellow substance, soluble in water, alcohol, and ether. With acids it forms definite crystalline salts, and gives precipitates with mercuric chloride, and with gold and platinum chlorides. In warm-blooded animals it produces vomiting, shivering, slackening of the respiratory movements, and ultimately stoppage of the heart.

Action of Aniline upon Epichlorhydrine.—Ad. Fauconnier.—In a former memoir the author described an oily base which he had obtained by the reaction of these two bodies, the hydrochlorate of which answers to the formula $C_{15}H_{20}N_2Cl_2O$. He has since obtained this compound in a crystalline state, and assigns to it the formula $C_{15}H_{18}N_2O$. He regards it as an alcoholic hydroxyl, possessing at the same time twice the function of a secondary base.

Constitution of Spongine.—Pierre Zalocostas.—Spongine is the nitrogenous organic matter of sponges. It approaches closely in its constitution to the collagenous bodies.

Volatile Bases of Cod-Liver Oil, Butylamine, Amylamine, Hexylamine, and Dihydrolutidine.—Arm. Gautier and L. Mourgues.—The authors give a description in detail of the above-mentioned bases. They remark that dihydrolutidine is moderately poisonous.

Neutralisation of Malonic Acid by Soluble Bases.—M. Massol.—The author's results show that the neutralisation-heats of malonic acid are lower than those of oxalic acid, but higher than those of succinic acid.

Preparation and Properties of Ethyl Fluoride.—H. Massan.—The author remarks that hitherto no researches of moment have been published on the fluorine compounds of the fatty series. Ethyl fluoride is a combustible gas, burning with a blue flame if pure. A trace of ethyl or methyl chloride gives the flame a green colour. In the combustion of ethyl fluoride there are produced copious fumes of hydrofluoric acid, which corrode the tube. In presence of an excess of oxygen it detonates violently on contact with a flame. If heated to 100° in a sealed tube, along with a very dilute solution of potassa, the compound is decomposed, yielding potassium fluoride, alcohol, and ether.

Acid Dimethyl-aniline and Diphenylamine Sulphates. General Reaction of the Acid Sulphates of some Aromatic Bases.—Leo Vignon.—The formation of the monosulpho-conjugated acids of dimethyl-aniline and diphenylamine obtained on heating the acid sulphates of these bases to 180° to 190° for two hours constitutes a general reaction. Under the same conditions acid aniline sulphate is transformed almost quantitatively into sulph-anilic acid.

Formation-Heats of the Isomeric Bases Toluidine, Benzylamine, and Methyl-aniline.—P. Petit.

Polybasic Glycerinates.—M. de Forcrand.—These two thermo-chemical papers do not admit of useful abridgment.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 1.

Determination of the Ferric Oxide in Iron Ores by the Tartaric Method.—L. Blum.—The author proceeds as follows:—4 to 5 grms. of ore are dissolved. After

separating the silica the liquid is diluted to 500 c.c. in a measuring flask and 50 c.c. are drawn off with a pipette for the determination of the iron. This portion is mixed with so much tartaric acid that no precipitate may be formed on the addition of ammonia. It is then diluted with water and precipitated with ammonium sulphide. The iron sulphide filtered off is washed with water containing ammonium sulphide, dissolved in dilute hydrochloric acid, precipitated with ammonia, filtered, and weighed as ferric oxide. Discrepancies between the results of identical samples may occur in consequence of the presence of phosphoric acid and magnesia. To prevent such errors the iron sulphide is precipitated in heat from a very dilute solution, and it is allowed to settle in heat, half an hour being sufficient.

Volumetric Determination of Sulphuric Acid.—A. Gawalowski.—The author's method, like those of C. Mohr and A. Clemm, is founded on the transformation of the sulphates by an excess of barium chloride, titrating back the excess of barium by means of an alkaline carbonate. The requisites are the solution of a barium salt, and that of an alkaline carbonate. These solutions are standardised by means of the solutions of a sulphate of known composition, and an indicator which is sensitive to alkaline carbonates. The solutions may be normal, semi-normal, or deci-normal. The sulphate to be analysed, which is necessarily neutral, is dissolved in water. An acid salt, or one containing free sulphuric acid, must be neutralised, and if the solution is alkaline it must be neutralised with hydrochloric or nitric acid. Of saline solutions a quantity is used, representing 0.5 of the dry substance. Phenolphthalein is added (except the ammonia is present), and the solution is afterwards neutralised, if requisite. An excess of the barium solution is then added, say 1 to 1.5 c.c. of the semi-normal barium solution to 1-10th grm. of the dry substance diluted with 30 to 40 c.c. of distilled water, well stirred, let stand from fifteen to thirty minutes, mixed with a few drops of pure alcohol, and titrated back with the soda solution until there appears a distinct permanent rose colour. The titration is best performed in an Erlenmeyer flask set upon blue paper. If ammoniacal salts are present the author uses lacmoid as indicator, and conducts the titration in monochromatic light.

The Oil of the Seeds of *Jatropha Curcas*.—F. M. Horn.—This oil is now (*Chemiker Zeitung*) used for burning, soap-making, adulterating olive oil, and probably for the preparation of alizarin oil. It is distinguished from castor oil by being almost insoluble in alcohol by its lower specific gravity and by its higher saponification and iodine number.

Detection of Fahlberg's Saccharine in Articles of Food.—E. Börnstein.—A sensitive reaction may be founded upon an observation communicated by Prof. Ira Remsen in the *American Chemical Journal*. On heating ortho-sulphobenzoic acid with resorcline and sulphuric acid there is formed a compound analogous to fluorescein. A small quantity of saccharine heated with a slight excess of resorcline and a few drops of strong sulphuric acid in a test-tube turns yellow, red, and then dark green, gives off sulphurous acid in plenty, and enters into vigorous ebullition, which continues for a short time after the removal of the flame. This ebullition is reproduced twice more, the liquid is let cool, diluted with water, and super-saturated with alkali, yielding a solution reddish by transmitted light, and displaying a strong green fluorescence by reflected light. This fluorescence is so sensitive that, in presence of 0.001 grm. saccharine the liquid can be diluted to 5 to 6 litres without the recognition of the fluorescence being in the least interfered with. The saccharine is best extracted from articles of food by means of ether. Solids and sparingly soluble substances are pulverised, moistened with a few c.c. of dilute sulphuric or phosphoric acid, dried, and exhausted by shaking with ether in a closed vessel. Fatty matter, if present, must first be removed by treatment with petroleum ether.

MISCELLANEOUS.

The Rarer Minerals.—At a recent meeting of the New York Microscopical Society, Mr. George F. Kunz, the able mineralogist of Messrs. Tiffany and Co., of New York, exhibited sand from Brindletown, Burke Co., N.C., containing monazite, which is a phosphate of cerium, lanthanum, didymium, and thorium, of which it contains from 0 to 17 per cent, and also exhibited monazite sand from Caravelhas, Brazil. He stated that the demand for these minerals had greatly increased of late, owing to the rare earths—zirconia, thorium, glucina, &c.—which they contain, and which are now used for the mantle or hood of the new incandescent gas burner invented by Dr. Carl Auer, called the "Welsbach" light. This increased consumption has led to a search by the collectors and dealers in England, Germany, France, Russia, Norway, and Brazil, and more especially in the United States, and so thorough has the search been that the prices of minerals which were considered rare a short time ago are now quoted at one tenth to one-hundredth of former figures. The minerals containing these earths are—Lanthanite, sipylite, tysonite, uranothorite, orangite, thorite, cleveite, beryl, yttrantalite, alvite, erdmannite, cerite, monazite, xenotime, fergusonite, æschynite, allanite, zircon, eudialyte, euxenite, samarskite, gadolinite, and bodenite. Of these beryl, cerite, monazite, xenotime, allanite, and zircon have been obtained in large quantities. Sipylite, orangite, and thorite are especially sought for. Monazite has been found at the following localities:—At Villeneuve, Ottawa County, Canada, a crystal of 14½ pounds; Alexander County, N.C., at Milholland's mill; Amelia County, Va., in 20-pound crystals; Norwich, Conn.; Ural Mountains, Tavetch (var. turnerite), Mount Sorel (var. turnerite), Binnenthal, Switzerland, Southern Ural, River Samarka, Arendal, Norway, but at all these localities the occurrence is of mineralogical interest only. In Burk, Polk, and McDowell counties, North Carolina; at Glade Mine, Georgia, and at Caravelhas, Bahia, Brazil, it can be obtained in the form of sand in commercial quantities. In the North Carolina gold gravels of Rutherford, Polk, Alexander, Burke, McDowell, and Mecklenberg counties, monazite is found in considerable quantities in small brown or greenish or yellowish brown monoclinic crystals, associated with chromite, garnet, zircon, anatase, corundum, menacanite, xenotime, fergusonite, epidote, columbite, samarskite, and other materials. With these associations have been found several of the North Carolina diamonds, and from these localities will be furnished tons of monazite within the next twelve months. The Brazilian monazite is found at Caravelhas, Bahia, where its existence was made known about eight years ago by Dr. Orville A. Derby, geologist of Brazil. It occurs in large quantities as a beach sand almost free from other minerals, as if concentrated. As it occurs on the coast, it can easily be shipped directly to any point desired, and over 6 tons have already been sent to the United States. The Meredith Freeman estate on Green River, Henderson County, North Carolina, is one of the best zircon localities, and for twenty-five years was in the hands of Gen. T. L. Clingman, who mined 1000 lbs. in 1869, believing firmly in the incandescent properties of zircon. Unfortunately for him, when the time for utilising this mineral had at last arrived, Gen. Clingman had forfeited his leases. At Anderson, in Anderson County, S.C., zircons are found in immense quantities loose in the soil, under similar conditions to those in North Carolina; they evidently come from a decomposed felspathic rock. The crystals are generally remarkable for their perfection, weighing occasionally several ounces. The recent demand has also brought to light the existence of enormous quantities of zircon in the Ural Mountains and in Norway. Although in Canada, in Renfrew and adjoining counties, immense crystals have been found, single crystals being up to 15 lbs. each, yet they are so isolated that it would be im-

possible to obtain them in any quantity. As already stated, the use of the Welsbach incandescent light has created a new demand for these minerals, and with rare prudence the parties interested quietly gathered a stock before the demand was generally known. It is said that there have now been accumulated more than 25 tons of zircon, 10 tons of monazite, 6 tons of cerite, and thousands of pounds of samarskite and other minerals. As a consequence zircon is now offered at less than 10 cents a pound, monazite at 25 cents, and samarskite at 50 cents, and many of the uncommon minerals at equally low rates. It is said that the zirconia in one ton of zircon would, if used alone, make half a million Welsbach burners, but several other minerals are mixed with it to produce varied and beautiful effects of colour in the light.—*Engineering and Mining Journal.*

CITY AND GUILDS OF LONDON INSTITUTE.

TECHNICAL COLLEGE, FINSBURY.

S. P. THOMPSON, Principal.

DAY DEPARTMENT FOR STUDENTS NOT UNDER 14 YEARS of age.

The College Courses of Instruction in Laboratory, Lecture-Room, Workshop, and Drawing Office, for Mechanical Engineers, Electrical Engineers, and Technical Chemists, COMMENCE on TUESDAY, OCTOBER 2nd.

Chemical Laboratories, specially organised for Instruction in Technical Manufacturing Processes. Fee for Session, inclusive of Laboratories, Workshops, and Drawing Office, £9.

The Entrance Examination will take place on Wednesday, September 26th, at Ten o'clock a.m.

Scholarships of £30 a year each, and the Holl Scholarship of £20 a year, all tenable for two years, will be awarded (in accordance with the several schemes) on the results of the Entrance Examination.

For particulars of Scholarships and programmes of Instruction apply at the Technical College, Leonard Street, City Road, E.C., or at Gresham College, E.C.

THE CHEMICAL NEWS.

Vol. LVIII. No. 1499.

CONTRIBUTIONS TO A KNOWLEDGE OF THE RARE EARTHS WHICH PRODUCE ABSORPTION-SPECTRA.

By PAUL KIESEWETTER and GERHARD KRÜSS.

The following researches are especially interesting as affording a decisive, though unconscious, verification of the results of Mr. Crookes, as it will be shown below.

These earths are found to consist of a far larger number of components than it would appear from the investigation of Soret, Lecoq de Boisbaudran, and Auer von Welsbach. The spectroscopic examination of the several fractions obtained by the fractionated decomposition of the nitrates from the earths of Fergusonite and Euxenite, has shown the difficulty of completely resolving the whole didymia and erbia into their several ingredients by the means hitherto employed. We may approach more closely to the object aimed at if we observe that nature has deposited some of these constituents either together or partially separated in one or other minerals, and in this or that locality. Thus from the author's former researches it appears that the minerals contain only the elements:—

Thorite from Brevig	$X\alpha, X\delta, X\eta.$
Thorite from Arendal	$\{ X\beta, X\gamma, X\epsilon,$ $X\zeta, X\eta.$
Wöhlerite from Brevig	$X\gamma, X\zeta, X\eta.$
Cerite from Bastnäs	$X\alpha, X\eta.$
Fergusonite from Arendal	$\{ X\beta, X\gamma, X\delta,$ $X\epsilon, X\zeta, X\eta.$
Fergusonite from Ytterby and Euxenite from Hitterö and Arendal	$\{ X\alpha, X\beta, X\gamma,$ $X\delta, X\epsilon, X\zeta, X\eta.$

Thus nature has already effected a partial separation of these mutually approximating elements, and in order to utilise this circumstance as far as possible in the study of the rare earths it is necessary to make an extensive spectroscopic investigation of the basic constituents of rare minerals from the most different localities. The following experiments have been undertaken from this point of view. The following minerals were examined:—

Yttrotitanite or Keilhaute from Arendal.—Dark brown pieces of keilhaute with vitreous cleavage-surfaces, in part with crystalline planes of a fatty lustre, were finely powdered and fused in a graphite crucible in a Perrot furnace with four parts of a mixture of sulphur and soda. This was done to search for germanium, which was not present.

After the mass had been lixiviated the dried residue was fused with four parts of acid potassium sulphate, and the rare earths of yttrotitanite were obtained in the watery extract of the melt. After precipitation from a hydrochloric solution by means of oxalic acid the mixed earthy oxalates, after drying and ignition, left a greyish-white powder with a slight yellowish cast. The ignited oxides were gradually brought into perfect solution by repeated treatment with strong nitric acid, and heating almost to dryness. The nitrate obtained, after being taken up in water, was repeatedly concentrated for a considerable time upon the water-bath, so that no free nitric acid was present in the solution as finally obtained. This solution showed the spectrum given below.

It is to be noted that samarium does not occur among the keilhaute earths, and that in this mineral there have been found only eight constituents of the Di, Er, Tm, and X earth. This is a relatively small number if compared with that forming the highly complex earths of other rare minerals. The most intense lines were $Di\delta=521.5$ and $X\zeta=452.6$, whilst almost all the other bands were faint or very faint. The substances, $Di\delta$ and $X\zeta$, whose nitrates gave lines at $\lambda=521.5$ and at $\lambda=452.6$, will therefore probably be more easily isolated from the keilhaute earths than from those of other minerals.

The isolated intense occurrence of the line $X\zeta$ is further noteworthy as affording further support for the view of Krüss and Nilson as to the complexity of Soret's earth, X. Let, e.g., the keilhaute spectrum and that of the earths of the Brevig thorite and wöhlerite be compared with that of an ordinary holmium material; it will then be seen that the holmium lines marked as X do not belong to the nitrate of one, but of several elements. This appears from the following diagram, in which are introduced in a scheme of the Fraunhofer lines on the one hand the X lines altogether, and on the other the X lines occurring in the spectrum of thorite (Brevig), wöhlerite, and keilhaute, according to their relative intensity. (See next page).

From this diagram it appears that the ingredients of the old holmium which occur in thorite, wöhlerite, and keilhaute differ from each other, whilst that body whose nitrate gives the line $X\epsilon$ does not occur in keilhaute and in the Brevig thorite and wöhlerite. This portion of Soret's X, according to the researches of Krüss and Nilson, is found in thorite, fergusonite, and euxenite of Arendal, and in the fergusonites of Ytterby, and the euxenites of Hitterö.

As to the occurrence of didymium in keilhaute, according to the above measurements there was observed only the presence of the constituents $Di\gamma$ and $Di\delta$. As only the lines belonging to the nitrates of these bodies are present in the spectrum of keilhaute, we have here a further proof of the more complex nature of didymium. Thus, in the neutral solutions of the nitrates of the earths of Brevig thorite the $Di\gamma$ lines at $\lambda=579.2$ and 575.4 were rather faint and faint, whilst at the same time

Keilhaute from Arendal.

Observed Position of Maximum
Darkness.

Position of Drum.	Wave-length Observed.	Wave-length Observed by Krüss and Nilson.	For	Intensities of Absorption-bands.
421	683.1	684	Tm α	Very faint; identified as a Tm line by comparison with Tm from the thorite of Arendal.
519	654.4	654.7	Er α	Faint.
863	580.3	579.2	Di γ	Rather faint.
895	575.3	575.4	Di γ	Faint, fainter than $\lambda=579.2$
1106	542.7	542.6	X β	Very faint.
1128	539.3	539.9	?	Very faint; observed in the spectra of the holmium material, and identified by direct comparison.
1240	523.0	523.1	Er β	Rather strong.
1254	521.3	521.5	Di δ	Strong, stronger than $\lambda=579.2$; a further proof of the difference of $Di\gamma$ and $Di\delta$.
1589	485.9	485.5	X δ	Rather faint, but much stronger than X β .
2088	452.0	452.6	X ζ	Stronger, stronger than X δ .

the lines marked $Di\theta$ and $Di\iota$ at $\lambda=445.1$ and 444.7 were very distinct. On the other hand, in the spectrum of keilhauite the $Di\gamma$ lines were rather faint and faint, but the lines $D\theta$ and $Di\iota$ were not to be observed at all. This phenomenon could not occur if $\lambda=579.2, 575.4, 445.1$, and 444.7 belonged to the nitrate of one single element. Further evidence for the more complex nature of didymium may be drawn from the strong isolated occurrence of $Di\delta$ at $\lambda=521.5$. From the study of the spectrum of keilhauite may be drawn a number of proofs for the complexity of those rare earths which produce absorption spectra. Spectroscopic traces of uranium were found in ytrotantalite.

(To be continued).

ELECTRICAL DIALYSIS.

By H. N. WARREN, Research Analyst.

DURING some experiments on reduction by means of nascent hydrogen, I have lately endeavoured to expose the same to an electro-dialytic action for the purpose of converting one substance into an allied form by the aid of the nascent hydrogen thus evolved, and at the same time to effect a separation by means of dialysis.

The apparatus made use of consists of an ordinary tubulated phial, from which the bottom had been separated and replaced by a parchment diaphragm, the further end being furnished with a perforated cork through which was inserted a glass tube terminating in a point containing metallic mercury in direct communication with a platinum wire fused into the glass and projecting into the mercury. The extremity of the wire is attached to a platinum plate dipping into the second tube intended to receive the solution to be thus acted upon. The decomposing tube itself is supported in a third vessel, containing an aqueous solution of whatever substance is desired to combine with the one dialysed. The same vessel also contains a porous pot, partially filled with ammonium chloride, into which a zinc rod has been introduced, the extremity being furnished with a binding screw, and in connection with the positive pole of a constant battery, the small tube containing the mercury being likewise connected to the negative extremity of the same. Before using the apparatus care should be taken to see that the three solutions contained in their respective tubes are exactly the same height as regards their aqueous layers, otherwise secondary actions present themselves, and either considerably retard the action or render it useless. The apparatus being now in order, and connection having been maintained by the aid of a large Bunsen cell, employing acidulated water for the decom-

posing or inner cell, large volumes of hydrogen gas are at once evolved from the platinum plate; and if now the acidulated water is wholly transferred to the outer cell, or retaining vessel, and replaced by a solution of cupric sulphate in admixture with sodium chloride, a violent evolution of gas is, as before, set free, which quickly subsides, the hydrogen assuming a nascent state, and soon decolorising the solution, the product being metallic copper, which attaches itself firmly to the platinum electrode, while sodium sulphate is formed by mutual decomposition; this, being a crystalloid, rapidly dialyses into the acidified solution contained in the outer cell. A solution containing potassium dichromate, acidified with sulphuric acid, was also rapidly converted into potassium sulphate and chromic hydrate, the potassium salt separating itself as in the previous experiment. Also, on exposing a solution of potassium ferricyanide to a like action, a quantity of potassium ferrocyanide had collected in the outer cell. Various organic substances were also thus treated, among which may be mentioned an alcoholic solution of ricinoleic acid, the outer cell containing sodium carbonate, the oleic acid becoming almost entirely converted into stearic acid, and combining with the sodium carbonate, thus liberating its carbonic acid, and forming sodium stearate.

DR. PETERS'S AMERICAN METHODS OF COPPER SMELTING. THE VALUATION OF FURNACE MATERIAL.

By JAMES W. WESTMORELAND, F.I.C.,
Associate of the Royal School of Mines, London.

IN the review of the above work which appeared some time ago in the *CHEMICAL NEWS*, vol. lvii., p. 22, certain statements are made, regarding which I will, with your permission, make a few observations.

Dr. Peters, in speaking of the English or Cornish system of fire assay, states that "in spite of the decided and constant inaccuracy of its results, it is so interwoven with the commercial customs of the Swansea copper smelters, and its replacement by one of the more accurate wet methods would involve such a revolution in the price lists and methods of ore buying, that it is likely to maintain its sway in the great ore market of the world for an indefinite time," while other recent writers have compared the fire assay to "a miniature of the smelting and refining operations which the ore has to be subjected to,

and is therefore a fairly practical method of arriving at its market value."

It is, of course, impossible to say when the Swansea fire assay will be replaced by more accurate wet methods of testing, but the other statements relating to the customs of the ore market are more open to criticism. Dr. Peters states that the adoption of a wet assay basis would cause a revolution in the price lists and methods of ore buying. But what are the facts? The Swansea ticketings or price lists are now things of the past, furnace material being now sold at a fixed price per unit of copper by private treaty. The remaining customs of the ore trade are:—The fire assay basis for percentage; ore tons of 21 cwt. 24½ lbs. (equal to 2376½ lbs. avoirdupois) in place of the statute ton of 2240 lbs., and an allowance of the actual moisture present in the mineral, which is invoiced and assayed in the dry state. But since July, 1886, the ton of 2376½ lbs. has to some extent been abandoned, sales of Annaconda matte being made on the actual dry weight of the parcel in pounds avoirdupois, the copper contents being invoiced at per pound of fine copper present in the parcel; a simple calculation showing the relation between the old and new systems of invoicing, a table being also drawn up showing the equivalent prices by each method. The only change really involved in a wet assay basis, therefore, would be the substitution of a more accurate process of assay with a fixed and definite "margin," or allowance, in place of the present inaccurate and unreliable fire assay method.

But serious errors have been made by other recent writers who have compared the fire assay to a miniature of the smelting and refining operations which the ore has to undergo, and which is therefore assumed to be a fairly practical method of arriving at its commercial value. The most elementary knowledge of metallurgy and assaying should have prevented such a comparison being made; the processes have little or nothing in common, and in recent years this view of the fire assay has certainly been kept in the background. The fusion for regulus, calcination, fusion for coarse copper, and refining, are in the fire assay entirely different operations to those conducted on a large scale, while the influence of "mass" has a most important bearing both on the fire assay and the furnace yield; for example, fire assay tests conducted with half and whole trial (200 and 400 grains) portions invariably show a higher percentage of metal on the heavier test, while carefully conducted chemical tests with similar portions of mineral will give practically identical results. Again, two fire tests made on the same finely pulverised sample by the same individual assayer gave 33 per cent and 35½ per cent respectively, equal in money value to £643 and £694—a difference on the parcel of £51. Will anyone contend that results of this character can give any practical indication of the market value of a parcel of mineral.

It is impossible to enter into all the phases of this question within the limits of this article, but it may practically be said:—That the results of the fire assay are very inaccurate and irregular, duplicate assays by the same operator varying considerably; that the margin between the fire and wet assays is extremely variable, and can be varied to a great extent at the will of the assayer; that the fire assay, when applied to the examination of bar coppers, will not detect or condemn impure coppers containing arsenic and antimony in large proportions; or confirm the quality of pure metals. Again, it has been admitted by the smelters that the results of fire assays are distinctly below the furnace yield; and by reason of these defects I contend that the process cannot form the basis of an equitable contract for the sale or purchase of furnace material.

Again, the great uncertainty of the process is well known to vendors and purchasers of mineral, the result being that extreme pressure is often brought to bear on the assayers with regard to the produce they shall return, and in fact the skill of an assayer is judged simply by the greater or less margins between the fire and wet assays

which he is able to obtain for his principals, according to whether they are purchasers or vendors. This, again, has resulted in actual tampering with the results of wet assays, in some cases to mislead principals regarding the actual "margin" on parcels of material; and again, to mislead assayers regarding the margins they were obtaining on material in process of testing.

I have always contended that it is most dangerous to admit the principle of interfering with the indications of any test; vendors and purchasers should meet each other fairly and fight out the question of price. When this has been settled, the true produce of the mineral should be ascertained without reference to any other consideration, for when once interference begins different vendors and purchasers of mineral exercising varying amounts of influence render the method of valuation inequitable.

As I write, I have the results of a series of tests of 20 parcels of the same material before me, and the differences between the fire and wet assays are so extremely variable that the fire assay produces cannot, in any sense, indicate the true value of each parcel. At the same time I must admit that until recently the wet assay tests made by many English operators were a reproach and a disgrace to the persons concerned—these bad results being, in the majority of cases, obtained by the "cyanide" method of testing, a process which is now, I believe, going into comparative disuse.

But, in the section of Dr. Peters's work relating to sampling and assaying, four methods of testing are described, which are, he states, quite sufficient for any technical or commercial laboratory, and yet that are every one essential if it be desired to fulfil every condition to the best advantage. These methods are the cyanide assay, colorimetric determination, precipitation with zinc or iron, and the electrolytic assay.

Little need be said regarding Dr. Peters's description of the cyanide assay, except that he states nothing which is unknown and omits much that is known to English chemists regarding the method, while the colorimetric and precipitation methods are only used to help other processes over some difficulty. But when we come to Dr. Peters's eulogistic description of the electrolytic assay, the statements he makes regarding it deserve careful consideration. He describes the method as being suitable for nearly every class of material and every percentage of copper, from the highest to the lowest, and, owing to its extreme accuracy, as largely supplanting the ordinary analytical methods. But, while making these statements, he quotes the results of Messrs. Torrey and Eaton, who have shown that silver, bismuth, lead, and arsenic all interfere with the accuracy of the method, and in these cases it is recommended that the deposited metal should be re-dissolved and the percentage of pure copper determined by that most objectionable of all methods of testing, the cyanide assay. But, in addition to the above impurities, the writer has met with cases where tin has been deposited with the copper, where flakes of oxide of manganese, a common constituent of American mattes, have been weighed with it, while ferric salts, which in many cases form the greater part of solutions of copper minerals, have a most injurious influence in delaying the precipitation of the metal.

Other evidence regarding the doubtful value of the electrolytic assay will be found in a paper entitled "A Comparison of Various Methods of Copper Analysis," by W. C. Eustis, Boston, Mass. (*Transactions of the American Institute of Mining Engineers*, vol. xi., p. 120), in which the results of a number of American analysts operating on an artificial mixture are given, together with the methods of analysis employed. Here evidence is given in a letter from Mr. Thos. B. Stillmann, of the deposition of other metals with the copper, while other chemists use various methods for testing the purity of the metal and for estimating the traces of copper generally left unprecipitated by the current. Again, Claussen (*Journal of the Society of Chemical Industry*, vol. vii., p. 402, May,

1888) treats the electro-deposited metal with a solution of bromine in hydrochloric acid to remove any arsenic, afterwards electrolysing the purified solution, while Bayley (*Industries*, 1887) advocates the use of sulphuretted hydrogen to estimate the small amount of copper generally left undeposited by the current. The writer admits that copper may be precipitated with accuracy from solutions, provided no interfering metals are present; but if this separation is absolutely necessary to avoid erroneous results the method is decidedly inferior to another well-known process to which allusion will presently be made.

Dr. Peters's evident satisfaction with the electrolytic assay will be apparent from the following quotation:—

"The following figures were handed to the author by a friend who was desirous of testing the accuracy of this assay, and who made seven determinations on the same sample of ore, weighing out different quantities in each case in order to obtain varying figures in the calculation of the percentage. The ore was an impure tetrahedrite, or the results would doubtless be even closer:—

(1) 9'66	(5) 9'98
(2) 9'67	(6) 9'85
(3) 9'74	(7) 9'82
(4) 9'61	

"It is evident that these results owe their remarkable uniformity to extreme care in manipulation and to the employment of the most perfect apparatus."

A friend to whom the above figures were communicated suggested that if the above figures are satisfactory it would be desirable to know what results Dr. Peters would consider unsatisfactory, and my personal opinion is that the results are neither creditable to the method employed nor to the operator concerned.

But Dr. Peters omits to mention a method of determining copper which day by day is coming into extended use in England. It is adopted by the principal analysts, in many copper smelting works, in works where wet extraction methods are employed, and it is equally applicable to the determination of copper in refined metals, almost chemically pure, and purple ore or blue billy with under one-tenth of one per cent of copper. Moreover, it is unaffected by the presence of silver, arsenic, bismuth, zinc, or manganese, while a simple method of separation by precipitation with hyposulphite of soda will separate the metal sufficiently from any conceivable combination of impurities to enable it to be at once accurately determined. I refer, of course, to E. O. Brown's iodide process, which was devised over thirty years ago for the examination of refined copper.

A large number of experiments made by me to ascertain the non-interference of various metals, are published in the *Journal of the Society of Chemical Industry*, February, 1886; while the accuracy of the process is referred to in more or less detail in the latest editions of Sutton's "Volumetric Analysis," Dittmar's "Quantitative Analysis," Phillips's and Bauerman's "Elements of Metallurgy," Mitchell's "Manual of Assaying," and in some articles on Assaying by T. Bayley, *Industries*, 1887. Curiously enough, none of the writers I have quoted recognise the importance of the titrations being made in an acetic acid solution, although they mention the advisability of this course. It is necessary to avoid the interference of arsenic acid, generally present to a greater or less extent, which would in the presence of mineral acids liberate iodine and vitiate the copper assay; while in an acetic acid solution, no such interference occurs.

But after reading Dr. Peters's eulogy of the electrolytic method as a matter of curiosity I made seven experiments similar to those quoted by him in order to see what the iodide process was really capable of doing.

A sample of finely pulverised cupreous pyrites was taken, and seven portions (50, 60, 70, 80, 90, 100, and 110 grains) dissolved in acids in the usual manner. Solutions of the following metals were then added to each test till

Electrolytic Tests for Copper. (Quoted by Dr. PETERS).

Iodide Tests. (J. W. WESTMORELAND).

the undermentioned percentages of impurities were present.

Tin	2'00 per cent.
Antimony	2'00 "
Bismuth	2'00 "
Lead	5'00 "
Arsenic	5'00 "
Zinc	5'00 "
Manganese	3'00 "
Nickel	3'00 "
Silver	0'50 "
Ferric salts	A large percentage

These impure solutions were then tested in the usual manner for copper ores, mattes, &c., and the following results were obtained:—

(1) 9'10	(5) 9'10
(2) 9'10	(6) 9'10
(3) 9'11	(7) 9'09
(4) 9'11	

Highest result		9'117	per cent.
Lowest		9'096	"
Difference		0'021	"

Electrolytical Results Quoted by Dr. Peters.

Highest result		9'98	per cent.
Lowest		9'61	"
Difference		0'37	"

At the present price of this material, about 14s. 6d. per unit, the difference in value between the maximum and minimum results quoted by Dr. Peters as electrolytic assays, would be nearly 5s. 6d. per ton of mineral, while the difference in value by my iodide results is less than fourpence.

The following diagrams, both drawn to the same vertical and horizontal scales, also show the relative accuracy of the results quoted by Dr. Peters and myself:—

It would certainly be interesting if any advocates of the electrolytical, sub-sulphide, cyanide, or other methods of determining copper would operate on similar solutions to those I have described above, and publish their results; at present I have the greatest doubt if concordant and accurate results can be obtained by other processes. The following tests also show the unreliability of the electrolytic assay:—

Copper Ore.

Electro-deposition direct		5'39
" after separation of As, Bi, Ag		5'10
Iodide process (J. W. W.)		5'09
Ditto. Result, obtained at an interval of six months in another laboratory, different operators, reagents, and apparatus. Test made without separation of Bi, As, Ag		5'12

Electro-deposition Direct.	Dissolved Metal Tested by Iodide Process.	Iodide Process.	Electro-deposition from Purified Copper Solution.
91'05	90'90	—	—
91'48	91'16	91'15 91'16	—
75'02	74'73	74'73	—
65'76	65'46	65'52	—
91'70	91'25	91'25	—
61'52	60'34	60'28	—
61'28	—	60'37	—
61'11	60'11	60'11	60'07

Practically, therefore, the introduction of a wet process of assaying would not interfere with any custom of the ore-trade; but if such a process was introduced, the iodide method would form a much more reliable basis than the electrolytic assay.

Leeds, August 2nd, 1883.

A NEW CONDENSER ATTACHMENT.

By JOSEPH F. GEISLER.

THE condenser attachment consists of a bulb-shaped cylinder about $2\frac{1}{2}$ inches in diameter and 4 inches in length (exclusive of lower contracted portion to fit into the stopper of the percolator containing the extraction tube), into the neck of which a tube (1 inch in diameter) containing a syphon, is attached by fusion. The tube reaches well down into the cylinder, and is perforated above the height of the syphon to admit the vapours into the condenser. The inner end of the syphon reaches very near to the bottom of the tube, and thus will thoroughly drain the same. The condenser attachment, made for me by Eimer and Amend, delivers about 15 c.c. of solvent at each syphoning, which is the most suitable quantity for ordinary work. Any desired quantity of solvent can be delivered

by increasing the size of the reception tube, or raising the height of the syphon, in which case the size of the extraction tube must also be increased to hold the increased quantity of solvent. The solvent drops from the condenser into the bulb-shaped attachment, and is discharged periodically by the automatic syphon upon the substance contained in the extraction tube below. The condenser attachment is of special advantage in the extraction of crude drugs, fats, alkaloids, resins, or substances to be removed by volatile solvents, such as ether, petroleum ether, chloroform, &c. One objection to the ordinary extraction tube and percolator with condenser is, that the time of extraction is unnecessarily prolonged by the continual dilution of the solvent in the extraction tube by the condensed portions from the condenser before that already in the extraction tube has had time to drain off. The difficulty is obviated by the condenser attachment, for little of the condensed solvent will get into the extraction tube proper until the reception tube is filled to the bend in the syphon, when the tube empties itself. By a little care this can so be regulated that the solvent in the extraction tube is drained off before a fresh supply is syphoned into the same from the tube above. By keeping sufficient solvent in the lower flask or receiver there is no danger whatever of the material in the extraction tube becoming overheated and ejecting the solvent, when the latter is delivered upon the same. The inner tube of the Liebig condenser, used with this piece of apparatus, should have an internal diameter of $\frac{5}{8}$, or better, $\frac{3}{4}$ inch, and the lower end should be cut off obliquely. The following are the sizes of the different parts of the complete extraction apparatus, convenient and suitable for the needs of ordinary work:—

1. A 6 oz. Erlenmeyer flask.
2. Extraction tube, $1\frac{1}{2}$ inches (inter. diameter) $\times$ 5 inches length.
3. Percolator, $1\frac{1}{2}$ inches internal diameter $\times$ 7 inches for body of cylinder, exclusive of lower contracted end of about $2\frac{1}{2}$ inches. Total length of percolator, $9\frac{1}{2}$ inches.
4. Condenser attachment, size to deliver about 15 c.c. solvent.
5. Liebig condenser, about 15 to 16 inches in total length, with inner tube of $\frac{5}{8}$ to $\frac{3}{4}$ inch internal diameter, and lower end cut off obliquely.

—*Journal of the American Chemical Society*, Vol. x., No. 3.

THE CLASSIFICATION AND NOMENCLATURE OF METALLINE MINERALS.*

By T. STERRY HUNT.

(Concluded from p. 68).

IN fixing the value of p for those metals which, like iron and chromium, like copper, mercury, gold, tin, palladium, and platinum, yield two distinct chlorides, we have in all cases taken the amount of metal which, in the ferrous, chromous, cuprous, aurous, stannous, palladous, and platinous compounds, is combined with one portion (35'5 parts) of chlorine. A similar rule, as already shown (§ 3), is applied in the case of arsenic, antimony, and bismuth. This unit-weight of the metal = p , when divided by d —the specific gravity, water = 1'000—gives the value of v .

(1). The metals and their alloys, which we include in the tribe of the Metalloideæ, present, unlike the other tribes of the order, wide differences in hardness, condensation, fusibility, and chemical characters, which can now only be briefly noticed. Of the hard and less fusible metals, chromium, manganese, iron, nickel, and cobalt, with $p = 26-29\cdot5$, gives values for $v = 3\cdot4-3\cdot6$; while the

* Read before the American Philosophical Society, May 4, 1888.

denser group of palladium, rhodium, and ruthenium, with $p=52-53$, and also the still heavier group of platinum, iridium, and osmium, in which $p=97-99$, agree in having $v=4.5-4.6$. The softer and more fusible metals, gold and silver, give $v=10-10.5$; the value of v for solid mercury being 13.9, for lead 9.2, for tin 8.0, and for cadmium, copper, and magnesium 6.5-6.9. With these, it is instructive to compare the values of v for the alkali metals, caesium = 70, rubidium = 56, potassium = 44, sodium = 24, and lithium = 12; as also barium, strontium, and calcium, in which v is from 12.5 to 17.5.

(2). The tribe of the Galenoideæ is conveniently divided into the three sub-tribes of sulphides, selenides, and tellurides, which we designate Thiogalenoideæ, Selenogalenoideæ, and Tellurogalenoideæ. Of these, the first includes the typical genus Thionites, embracing the native sulphides of lead, silver, and copper, together with metacinnabar, stibnite, and bismuthite; having $H=2-3$: $v=7-8$. The sub-tribe of the Selenogalenoideæ includes a genus which may be called Eucairites, embracing besides eucairite (cuproso-argentic selenide) various other selenides of lead, silver, copper, mercury, and bismuth; $H=2-3$: $v=8-9.5$. The sub-tribe of Tellurogalenoideæ includes various tellurides of silver, gold, lead, mercury, nickel, and bismuth, with $H=2.5-3.5$: $v=8-10.5$, which we include in the genus Tellurites. The soft, flexible, foliated sulphides, like sternbergite, argyropyrite, friesite, covellite, and perhaps molybdenite, may constitute a second genus of the first sub-tribe with the name of Thiophyllites; while tetradymite and nagyagite perhaps may form a similar division of the Tellurogalenoideæ, as Tellurophyllites.

(3). In the third tribe we include many sulphides which are near in hardness, in condensation, and in other characters, to the last, and are chiefly sulphides of lead, copper, and silver united with sulphide of antimony, of bismuth, or more rarely of arsenic. The antimonial species of this tribe are represented by the well-known species, bournonite; from which the name of the tribe, Bournonoideæ, and the genus Bournonites; having $H=2-3.5$: $v=7-8.5$. The large group of bismuthic species, having similar values for H and v , and many other points of resemblance, of which emplectite is a representative, constitute the genus Emplectites. These two genera present instructive examples of progressive series, especially in the double sulphides of antimony and lead, $Sb_2S_3 \cdot nPbS$, in which n has values of 1, 2, 3, 4, 5, 6, and, in a related species, even equals 12. The species enargite is an arsenical bournonoid, and to this tribe may perhaps belong some of the forms of fahlerz or grey copper ore.

(4). The next three tribes are distinguished from the two preceding—which correspond to the Glances of the natural-history system—by their much greater hardness and condensation, and were included in the order Pyrites of the same system, but are here divided on chemical grounds. The tribe of the Pyritoideæ may be divided into two genera, the harder designated as Pyrites with $H=5.5-6$: $v=3.8-4.5$ includes cubic and prismatic iron pyrites, with linnaëite, siegenite, carrolite, and laurite; while the genus Pyritinus, $H=3.5-4.0$: $v=4.5-5.5$, embraces troilite, pyrrhotite, allabandite, millerite, pentlandite, chalcopyrite, cubanite, and probably stannopyrite.

(5). The tribe of Smaltoideæ includes the various arsenides of cobalt, nickel, and iron, of which leucopyrite and smaltite are representatives, and which we have included in the genus Smaltites with $H=5-6$: $v=3.6-4.5$. The arsenides of copper, with less hardness and a higher value for v , will form a distinct genus, Algodonites. Closely related to smaltites is the antimonial species, breithauptite; while the antimonoid of copper, horsfordite, and apparently dyscrasite, are near to Algodonites.

(6). The tribe of Arsenopyritoideæ, embracing the genus Arsenopyrites, includes the compounds of sulphide of arsenic with sulphides of iron, cobalt, and nickel, of which arsenopyrite or mispickel is a type, $H=5-6$: $v=$

2.9-3.5. Near to these are some little known double sulphides holding antimony and bismuth, as ullmannite, corynite, alloclasite, and grunauite.

(7). Passing now to the sub-order Spato-metallineæ, we have in the tribe Spato-metalloideæ those forms of phosphorus and of selenium which are wanting in the metallic characters, including the colourless and the ordinary red phosphorus, apparently two forms of selenium, and the various known species of sulphur.

(8). The tribe Sphaleroideæ includes the genus Sphalerites, embracing sphalerite, wurtzite, christophite, greenockite, hanerite, oldhamite, and cinnabar, having $H=2.5-4.0$: $v=6-7$. Here also belong the red antimony sulphide, metastibnite,* and the arsenical sulphides, realgar and orpiment.

(9). The tribe Proustoideæ includes the genus Pyrarigites, under which we may include, in two sub-genera, both the arsenical and the antimonial red silver ores, including proustite, pyrarigite, miargyrite, &c.; with $H=2-3$: $v=8-9$. In this tribe also are included the arsenical and the antimonial forms of fahlerz as members of a genus, Tennantites, in which, moreover, are placed binnite, dufrénoysite, livingstonite, &c., having—

$$H=3.5-4.5 : v=6.5-7.5.$$

The following table gives a synoptical view of the tribes and genera above proposed for the order of the Metallata. Further studies may probably show reasons for further sub-division of some of these genera and for the establishment of new ones.

Order METALLATA.

Sub-order A. METALLOMETALLINEÆ.

Tribe 1. METALLOIDEÆ (Metals, alloys, metallic Se and P).

- „ 2. GALENOIDEÆ, including three sub-tribes:—
 - a. Thiogalenoideæ; Thionites, Thiophyllites.
 - b. Selenogalenoideæ; Eucairites.
 - c. Tellurogalenoideæ; Tellurites, Tellurophyllites.
- „ 3. BOURNONOIDEÆ; Bournonites, Emplectites.
- „ 4. PYRITOIDEÆ; Pyrites, Pyritinus.
- „ 5. SMALTOIDEÆ; Smaltites, Algodonites.
- „ 6. ARSENOPYRITOIDEÆ; Arsenopyrites.

Sub-order B. SPATOMETALLINEÆ.

Tribe 7. SPATOMETALLOIDEÆ (Sulphur, non-metallic Se and P).

- „ 8. SPHALEROIDEÆ; Sphalerites.
- „ 9. PROUSTOIDEÆ; Pyrarigites, Tennantites.

The writer has prepared tables, giving for each species in the order of the Metallata besides hardness, specific gravity, and crystalline system, the chemical formula, represented by a simplified notation, as indicated in §3, together with the unit value for p , and the value of v calculated therefrom. For each species, moreover, besides its trivial designation, are given its generic and specific Latin names. Thus, for example, we have for the species above named under the genus Pyrites:—*P. cubicus*, *P. prismaticus*, *P. cobalteus*, *P. niccolocobalteus*, *P. cuprocobalteus*, and *P. rutheneus*; while the named species of Pyritinus are:—*P. ferrosus*, *P. magneticus*, *P. manganeus*, *P. niccoleus*, *P. ferroniccoleus*, *P. cupreus*, *P. subcupreus*, and *P. stanneus*. Again, the above-named species of the genus Sphalerites are:—*S. zincus vulgaris*, *S. zincus hexagonus*, *S. ferrozincus*, *S. manganeus*, *S. calcareus*, *S. mercureus*, and *S. stibeus*. A similar task, except so far as regards generic and specific names, has already been accomplished for the order of the silicates in the essay published in 1886, already cited, and is now well

* The native red sulphide of antimony, Sb_2S_3 , occurs abundantly as an amorphous deposit from thermal alkaline sulphurous waters, with sulphides of arsenic and cinnabar, at Steamboat Springs, Washoe County, Nevada, according to a private communication from Dr. G. F. Becker, who suggests the name of metastibnite.

advanced for most of the other orders. When completed the whole will be published with explanatory and critical details, as a Systematic Mineralogy, to be followed by a Descriptive Mineralogy.

ON THE PRESENCE OF FUSEL OIL IN BEER.*

By WILLIAM M. HAMLET, F.C.S., Government Analyst.

THE beverages we know so well as fermented malt liquors are so complex in their composition, and so liable to change and decay, that until the last few years very little was known of their exact nature and internal constitution,—still everyone was supposed to know all along the difference between good and bad beer. From the time of Falstaff to the present day the beer drinker has always been a trifle suspicious of his brewer, and ever ready to exclaim with that fat and valiant judge of good liquor, "You rogue, here's lime in this sack," and he generally experiences a most lively satisfaction in changing his "barley bree."

It would help us to clearer views on this subject if we consider what beer really is, or rather what it ought to be, and what are the chemical and biological processes involved in its manufacture. I may therefore at once define beer as an alcoholic beverage made from malt, hops, yeast, and water.

As briefly as I can describe it, the process of brewing ordinary beer is as follows:—Malt is crushed between rollers, and dissolved in or extracted by water at a temperature which is more or less a secret with the individual brewer,—generally from about 140° or 145° to 150° F. By this means an infusion of malt is made, the operation being known as that of mashing; the vessel in which it is produced being termed the mash tun, while the product is known as the wort. The water found most suitable for mashing is one containing very little or no organic matter and a somewhat large proportion of sulphate of lime, which makes what is called a *hard* water: for porter brewing, however, a softer water is used. By using a hard water certain albuminous matters contained in the malt are prevented from coming into solution; that is, the albumenoids are rendered much less soluble.

The chief object of the brewer in mashing is to convert the starch present in the malt into a peculiar variety of sugar termed maltose, this change being effected by the presence of a body known as *diastase*. A very small amount of this diastase is sufficient to convert an unfermentable body like starch into maltose: 1 part will transform 10,000 parts of starch into maltose—a sugar which is directly fermentable.

The next step is to boil the wort in a separate vessel termed the copper, together with a certain quantity of hops. The object of adding the hops is to impart the well-known bitter flavour, to endow the beer with narcotic properties, and finally to act as a preservative agent and so enhance the keeping qualities of the beer.† After boiling, the worts are rapidly cooled down to a temperature varying from 58° to 62° F., and run into the fermenting "rounds" or "squares." Yeast is now added, or, in the language of the brewer, fermentation is said to be "pitched" at a temperature varying with the locality and the practice and ideas of the brewer.

Fermentation proceeds rapidly, attended by a rise in temperature; and here comes one of the most critical parts of the process of brewing. It is after the worts have arrived at the fermenting tuns that the brewer's skill and experience comes in. I do not mean that any amount of skill in regulating the fermentation will ever remedy carelessness in mashing, because if the wort is not per-

fectly sound on its arrival at the fermenting tuns a perfect fermentation cannot be obtained; but only that, be they ever so satisfactory at this point, negligence or unskilfulness will be then even more fatal than at any other previous stage. Here it is that, with a climate like that of Sydney, ice or artificial cooling machinery becomes absolutely essential for the production of good beer. Experience has shown that fermentation should never exceed 70° to 72° F. When this temperature is exceeded no amount of after treatment or doctoring of the beer will ever remove its own inherent bad quality.*

What goes on in the act of fermentation will be better understood if we regard the wort merely as a sugar solution with some other albuminous bodies that may be more conveniently considered hereafter.

Alcoholic fermentation is the outcome of the life of a minute plant,—a very lowly organism called the yeast-cell or *Saccharomyces cerevisia*. The sugar solution is its arena, and ethylic alcohol is one of the products of its own life-decomposition, just as much as urea is one of the life-products of a man. As plants possess the faculty of changing the carbon dioxide of the atmosphere into starch, sugar, alkaloids, and other products, so this little cryptogam lives upon the maltose of the brewer's wort, changing it into alcohol and other compounds.

The illustrious Pasteur found that 100 parts of cane-sugar, first converted into the fermentable variety of sugar, will yield—

Ethylic alcohol	48.40	per cent.
Carbon dioxide	46.60	"
Succinic acid	0.67	"
Glycerin	3.30	"
Cellulose fat, &c.	1.20	"

Now it is just at this critical stage of fermentation that other higher alcohols may be produced. Pasteur, Schützenberger, and Berthelot all recognise the fact of the simultaneous evolution of the higher alcohols under varying or under abnormal conditions. Schützenberger says:—"We may ask whether these secondary products [*i.e.*, fusel oil], which are relatively not very abundant, owe their origin to alcoholic fermentation properly so called, or to distinct concomitant fermentation having each a special ferment; or whether, in fact, it is better to attribute their appearance to special principles accompanying glucose in the natural saccharine juices. The actual state of science does not allow us as yet to answer these questions definitely.

Pasteur† mentions the production of butylic alcohol in irregular fermentation, and its non-appearance in carefully conducted fermentation.

Before proceeding further it will be well to see what is the actual composition of properly brewed genuine beer, so far as it has been investigated by modern chemical research.

Percentage composition of genuine beer:—

Extract	Dextrin	from 2	to 5
	Albumenoids	" 0.2	" 0.4
	Maltose	" 1	" 3
	Lactic acid	" 0.02	" 0.05
	Succinic acid	" 0.04	" 1
	Glycerin	" 0.2	" 0.25
	Colouring-matter		
	Hop extract	" 1	" 1.2
	Ash (mineral matter) ..	" 0.2	" 0.27
Total extract ..		" 5	to 8
	Alcohol (by weight)	" 3½	to 7
	[Alcohol equivalent in proof spirit	" 7½	" 15½]
	Acetic acid	" 0.02	" 0.04
	Carbonic acid	" 0.22	" 0.25

* Pasteur speaks of this as "a rigorous limit of fermentation temperature." "Etude sur la Bière," Paris, 1876, p. 14.

* Read before the Royal Society of N.S.W., November 2, 1887.

† Hops are to the high fermentation brewer what ice is to the brewer of lager beer.

The origin of the enquiry which forms the subject-title of this paper arose during the ordinary routine work in the Government laboratory. For several years the examination of beers was somewhat a rare occurrence, but in the year 1881 a Mr. Waters, from Melbourne, created no small excitement by stating that the beers made in Sydney contained vitriol, aloes, bluestone, and infusion of tobacco juice. The result of this alarming statement induced Mr. Barney, Chief Inspector of Distilleries, to send a number of spirituous liquors to my predecessor, Mr. Charles Watt, for analysis. It appears, from the enquiry then made, that the chief interest centred in the quality of the rum, whisky, and brandy; however, later on, in the following year, some eleven samples of Sydney beer were examined.

During the four years from 1882 to the end of 1886 a very large number of samples were examined in the Government laboratory. The general results showed that the statement of Mr. Waters was without foundation. The methods of analysis usually included the estimation of the percentage of alcohol, ash, and extract together, with some statement to the effect that none of the articles mentioned in the Licensing Act had been found. In fine, the worst that could be said of the beers was that sometimes traces of lead or copper were found.

Early in the present year the question of artificial bitters and hop substitutes engaged the attention of analysts in England, amongst whom my friends Dr. Muter and Mr. Otto Hehner were much interested in the subject. At the same time statements were frequently heard in Sydney to the effect that the brewers were in the habit of putting poisonous bitters into the beers instead of hops, and inasmuch as the police were constantly sending samples of beers and spirits for analysis, I wished to seek further satisfaction in the matter by carrying out a fuller and more extended investigation as to the nature of the bitter principle used in the manufacture of the local beer: with this object in view I requested that larger samples should be submitted for analysis. These were all specially examined for strychnine, picric acid, cocculus indicus, and tobacco, as well as for quassia, gentian, chiretta, &c. In the case of all the brewers it should be said, to their credit, that no poisonous bitter of any kind could be discovered, not even after a most laborious and lengthy research.

During the course of analysis it was observed that the proportion of dextrin was unusually large, while the amount of maltose and albumenoids were extremely small. This might, of course, be attributed to great attenuation in the process of fermentation. In the course of mashing with malt the proportion of dextrin to maltose goes on in very nearly a fixed ratio up to 140° F., when the maltose diminishes rapidly and the dextrin increases very considerably. Therefore are we to account for the dextrin by high mashing heats? or would it not more likely be owing to the fact that large quantities of sugar are used in the brewing process? If this be so, why does the brewer use sugar, and, if so, what kind of sugar?

The object of the brewer in using sugar may be considered under two heads: first, his object is to reduce the proportion of the albumenoid matter in the wort; and secondly, to effect a saving in the price of malt,—in other words, to use as little malt as possible, because barley is not grown here and has therefore to be imported, while sugar grows well, as everybody knows.

In the ordinary brewing process the reduction of albumenoids is mainly effected by the boiling of the wort after mashing; but it is also further considerably effected by the tannin of the hops, and by the employment of natural or else artificial waters, containing suitable saline bodies, principally sulphate of lime, which renders some of the albumenoids insoluble.

Notwithstanding these various methods of reducing the albumenoids, it is generally found by most brewers that a further reduction is necessary beyond what is attainable

by these means. Now the addition of sugar effects this by the simple process of diluting the albuminous wort with a substance which is non-albuminous, but yet fermentable. These albuminous bodies, from a sanitary or dietetic point of view, would prove of advantage to the beer consumer, inasmuch as these are flesh and tissue formers, being in fact the proteid matter from the grain. The reason why stout would be given to the invalid or the convalescent would be precisely on account of these albumenoids, which are studiously eliminated in the manufacture of Sydney beer. From the brewer's point of view he would say they were decidedly objectionable, since they would prove food for the yeast-cell, and for false or adventitious ferments. And still these albumenoids are essential for the healthy growth of the yeast, so that it is important that the brewer has a sufficient quantity in his worts for the yeast to live upon, as otherwise the *S. cerevisia* would starve and die. The main object of the brewer is to conduct his fermentation without the introduction of the false ferments, so called,—the lactic, acetic, and butyric ferments. A beer so made, and afterwards kept from their contamination, would keep sound for an indefinite length of time.

Now, as to the why and wherefore of the use of sugar. The beer betrays its origin by its taste; albeit the demand may be for sweet ales, or sweet "running ales" as they are sometimes termed, the sweetness may not be due to cane-sugar; certainly not, since the sugar has undergone a change. If sugar crystals are used in brewing Sydney beer, and there is internal evidence from the beer itself that such is the case, the brewer must first convert them into a fermentable variety of sugar; the sugar must be inverted, as it is more correctly termed. Cane-sugar of itself is unfermentable. This inversion may be effected in four different ways:—

1. By malt extract in mashing at not too high a temperature.
2. By prolonged boiling with water.
3. By treatment with yeast and water.
4. By the action of sulphuric acid and after treatment with chalk.

The brewer is confronted with the question as to what sugar may be used, raw or refined crystals? If the former, other organisms besides the *S. cerevisia* would inevitably be introduced: this would be followed by a high and uncontrollable fermentation; with refined crystals the sugar, we have seen, has to be inverted. Another question then arose, Were these beers brewed at an abnormally high temperature? Remembering that an eminent authority on brewing, Dr. Charles Graham, had found that a high temperature in fermentation means not only a rapid attenuation of the wort, but an increased loss of alcohol by evaporation, together with an increase in the higher alcohols—the fusel oils; reasoning upon this hypothesis the presence of fusel oil would therefore indicate to some extent the mode of manufacture of the beer. The question then resolved itself into this—Does this beer contain fusel oil? Some difficulty then arose as to the process for finding out whether higher alcohols existed in beer. The methods in use which were applicable to liquids such as brandy and whisky failed when applied to beer. The method of fractional distillation was tried: the distillates from two litres of beer were placed in a flask fitted with a modified Hempel's column and the fractions collected separately, a current of steam being used to remove the last traces. As the boiling-points of the different alcohols were not sufficiently marked from each other, the idea presented itself of converting the alcohols into their respective iodides, since the boiling-points would be sufficiently removed from each other to enable a more complete separation to be effected.

However, these methods were afterwards abandoned, since it might be said that these higher alcohols might be generated in the act of distillation, an objection that I do not think carries much weight, as the alcohols are

products of fermentation and are not likely to suffer changes in distillation. However, these methods were set aside for a process that would remove the higher alcohols from the beer itself, *without* distillation. The process I finally adopted—a modification of my own of Marquardt's—was based upon the fact that amyl alcohol is soluble in chloroform. I operated on a gallon of the beer in the following manner:—Some of the beer to be tested is placed in a capacious separator, together with 50 c.c. of chloroform: after repeated shaking, the liquid is allowed to subside, and the beer poured off without disturbing the chloroform. More beer is added until half the gallon has been so treated, when a further 50 c.c. of chloroform is added, together with more of the beer, until about 5 pints have been used; a third 50 c.c. is taken, making altogether 150 c.c. of chloroform with which the remainder of the beer is thoroughly agitated. By this time the whole of the fusel oil will have been extracted. The next step is to wash the chloroform with water to remove traces of valerol derivable from the hops, and also to remove ethylic alcohol that may have been taken up into solution. The solution is then placed in a strong glass vessel with 5 grms. of potassium dichromate and 2 grms. of concentrated sulphuric acid, and oxidised under pressure for six hours at a temperature of 85° C. The oxidation having been completed, the liquid is now distilled, water added to the residue, and the distillation continued. The distillate, which has a strong odour of valerianic acid, is boiled for half an hour with some pure barium carbonate in a flask connected with an inverted Liebig condenser. After this the chloroform is removed by distillation, and the residue filtered. The filtrate is then evaporated to dryness in a platinum dish, weighed, and dissolved in water with a few drops of nitric acid. The solution is divided into two equal parts. In one the barium is estimated; in the other the amount of barium chloride. The weight of the latter is deducted from the residue. The total amount of barium salt, minus that existing as chloride, gives the amount of barium as barium valerianate, and from which the amount of amyl alcohol is readily found.

The chloroform and the rectified spirit used throughout this research was carefully tested by blank experiments for the presence of the higher alcohols. Care was taken that only pure chloroform was used.

(To be continued).

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 5, July 30, 1888.

The Relations of Atmospheric Nitrogen to Vegetable Soil.—Th. Schloesing.—In the varied and prolonged experiments of the author the soils examined have not fixed any gaseous nitrogen.

The Determination of Carbon and Nitrogen in Vegetable Soil.—Th. Schloesing.—The author mentions that in lands manured with street-sweepings the amount of carbon is greatly exaggerated in consequence of fragments of coke, coal, &c., thus introduced. The author partially avoids this error as follows:—200 grms. of the sifted soil are spread out in a muffle, the temperature of which scarcely reaches incipient redness. The organic matters are very combustible, and disappear totally. Coke remains, and may be afterwards determined separately. Wood-charcoal burns with the organic matters. In determining the nitrogen M. Schloesing uses from 150 to 250 grms. in order to secure a fair average specimen. He

uses combustion tubes of 2 metres in length; his gas furnace is 1.85 metres long, and has 88 Bunsen burners. The tube receives the ordinary charges of roasted copper-turnings, extending to 0.60 metre, this portion being wrapped in a ribbon of tinsel. Then follows, between two asbestos plugs, a small tube stoppered at one end, and containing 10 grms. pure lead carbonate. The soil occupies all the rest except 0.15 metre at the end left empty. The tube is laid above the burners on a bed of sand in a channel of brass. This channel is cut in three sections, the first under the copper turnings, the second, much shorter, under the lead carbonate, and the third under the earth. The drawn-out end is connected with a two-necked receiver in which is condensed the water given off in the operation; the receiver is also connected with the leaden capillary tube of a mercury-pump. To the other extremity of the tube is connected a green glass retort containing pure potassium chlorate.

The Density of Chlorine and the Vapour-density of Ferric Chloride.—C. Friedel and J. M. Crafts.—At elevated temperatures the authors find the density of chlorine 2.448, which approaches very closely to the theoretical value, 2.449. Between 321° and 442° ferric perchloride has a fairly constant density, corresponding to the formula Fe_2Cl_6 .

The Vapour-density of Gallium Perchloride.—C. Friedel and J. M. Crafts.—The authors' mean result is 12.36, theory requiring 12.2 for the formula Ga_2Cl_6 . Above 307° there is a notable decrease of density, the value at 357° being 8.5 and at 440° 6.6.

In What Stages of Oxidation do Chrome and Manganese Exist in their Fluorescent Compounds?—Lecoq de Boisbaudran.—This question does not receive any definite answer.

Determination of Lithium in Mineral Waters. Analysis of Two Springs in the Côte d'Or.—A. Carnot.—A known volume of water is concentrated by evaporation, eliminating successively the alkaline-earth carbonates, iron oxide, silica, sulphuric acid, magnesia, baryta, lime, and lastly the ammoniacal salts, always ascertaining that none of the deposits contain lithia. There remain in solution merely alkaline chlorides, perhaps accompanied by traces of magnesium chloride. This solution is gently evaporated until the salts begin to deposit, when it is constantly stirred with a platinum spatula, so as to have a fine crystalline powder. We stop before dryness and mix with alcohol at 99 per cent, grinding with a pestle and letting digest for some time, then filtering and draining with the filter-pump. A large part of the chlorides are thus removed, and we find, with the spectroscope, that they do not contain lithium. The alcohol is distilled off, the saline residue left is dissolved in a little water with two or three drops of hydrochloric acid, evaporated, and treated while still moist with strong alcohol. It is received on a filter, drained, and washed at first with alcohol alone, and then with the addition of ether, which dissolves out the last portions of lithium chloride. The ethereal alcohol is distilled off, leaving with the lithium chloride merely a small proportion of other alkaline chlorides. To this residue is applied the method described in *Comptes Rendus*, vol. cvii., No. 5.

Economical Production of the Chlorides of Oxidised Elements, such as Aluminium.—A. Faure.—The author uses hydrochloric acid instead of chlorine, and does not mix with carbon but with naphthalene.

Process for Separating and Determining Zinc.—J. Riban.—This paper will be inserted in full.

On Sodium-glycol-alcoholate.—M. de Forcrand.—A thermo-chemical paper, not capable of useful abstraction.

A Dibenzic Ether derived from Mannite.—J. Meunier.—This ether has the composition $\text{C}_{20}\text{H}_{22}\text{O}_6$.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 1.

Researches on the Equations of Indirect Analyses.—S. Panuschko.—This paper does not admit of useful abstraction.

Safety-Pinchcock.—N. von Klobulow.—This paper requires the five accompanying figures.

Apparatus for Extracting Fats in the Cold.—This paper requires its two figures.

Determination of the Quantities of Lime and Soda required for Softening Water.—Otto Binder.—To 200 c.c. water placed in a 300 c.c. flask are added 50 to 75 c.c. of saturated lime-water containing a known proportion of lime. This is determined with a sulphuric acid containing, per litre, 1.857 grms. sulphuric acid; 1 c.c. of this acid represents about 1 c.c. of lime-water, and is prepared by diluting 46.43 c.c. normal acid to 1 litre. The sample, mixed with lime-water, is heated (the mouth of the flask being loosely stoppered with a perforated cork holding a thermometer) to the temperature designed for the softening of the water on the large scale; therefore to 50° to 80° (?). When the contents are cold the flask is filled to the mark with distilled water free from carbon dioxide, and 250 c.c. are filtered through a dry folded filter. In the filtrate the excess of caustic lime is titrated back, the quantity used for 1 litre being found by calculation. In most cases a considerably larger quantity of lime is required than that which corresponds to the temporary hardness. *Determination of the Soda to be Added.*—For this purpose 250 to 300 c.c. of water is evaporated in a platinum dish to dryness with 5 c.c. of a normal soda solution. The residue is dissolved in water, filtered, washed, the undecomposed sodium carbonate is determined volumetrically with acid and methyl orange. The difference shows the proportion of soda needed for the decomposition of the chloride, sulphates, and nitrates. About 10 grms. soda per cubic metre should be used over and above the quantity thus determined.

Overflow-point for Burettes.—Otto Binder.—This paper requires the three accompanying figures.

Funnel Support for Drying Precipitates in the Funnel.—The writer proposes to make the horizontal rods of Meurer's funnel-support curvilinear instead of straight.

Determination of Traces of Arsenic in Tissues, Yarns, and Paper-hangings.—R. Fresenius and E. Hintz.—This paper will be inserted in full.

Quantitative Determination of Acetone in Methylated Spirits, in Methyl Alcohol, and (Commercial) Acetone.—E. Hintz.—The quantity of acetone, from 0.2 to 0.3 per cent, occurring in commercial methylated spirits, as supplied to colour-works, can be well and accurately determined according to G. Krämer's method (*Berichte*, xliii., p. 1000) by converting the acetone into iodoform and weighing the latter. In accurate determinations it is well to make a blank experiment with the reagents in the absence of the methylated spirit, and, in afterwards calculating the acetone, to deduct the small quantity of iodoform and iodides thus obtained. Such a blank experiment yields about 0.002 gm. Krämer's method is satisfactory for samples containing 5 per cent of acetone, but for smaller proportions it is not trustworthy. It is therefore advisable to dilute any sample with water, so that its proportion of acetone may be from 1 to 1.5 per cent.

Detection of Nitric Acid in Wines.—Eugene Borgmann.—The author has examined Egger's method, which consists of treatment of the sample with diphenylamine and strong sulphuric acid. This reaction is most sensitive if a freshly prepared solution is used of 0.01 gm. diphenylamine in 100 c.c. pure monohydrated sulphuric acid. The wine must be previously decolourised by means of animal charcoal, which, as well as the other reagents, must be

absolutely free from nitric acid. Nitric acid, if present in small quantities, disappears in course of time.

On Thermometers and Thermometric Determinations.—A collection of extracts from the *Zeitschrift für Instrumentenkunde*, the *Philosophical Magazine*, the *Journal of the Society of Chemical Industry*, and the *American Chemical Journal*.

The Determination of Vapour-densities.—This memoir requires the two accompanying illustrations.

Gas-tight Glass Cocks.—A. Eiloart.—From the *CHEMICAL NEWS*.

Gas-absorption and Measuring Apparatus.—W. H. Greene.—From the *American Chemical Journal*.

A Modified Mercurial Air-pump.—A. Joannis.—The peculiarity of this apparatus is that instead of a vessel being alternately raised and lowered, both vessels are fixed and are connected by a U-tube. The advantage of this new construction is that the thick caoutchouc tube, necessary in all other models, is dispensed with, and that the movement of the mercury is gradual, thus obviating the danger of breaking the cocks.

Apparatus for Distilling Mercury.—B. Nebel.—This memoir requires the accompanying figure.

Quantitative Determination of Zinc.—Max Bragard.—The author particularly examines precipitation in a formic solution, especially for its separation of other metals from the ammonium sulphide group. In thus separating zinc from nickel the solution must be sufficiently acid to prevent the precipitation of nickel by sulphuretted hydrogen, the addition required being 5 c.c. formic acid (sp. gr. 1.1136) to 0.03 gm. nickel. The free acid must not exceed a certain limit if the zinc is to be thoroughly precipitated. But if increased acid is required by a large quantity of nickel the solution must be diluted to 500 to 600 c.c. If the precipitation is to be effected in heat more acid is required than for a cold solution. If the zinc sulphide is contaminated with nickel sulphide the precipitate is re-dissolved in hydrochloric acid, the sulphuretted hydrogen expelled, ammonia and formic acid are added, and a fresh current of sulphuretted hydrogen is passed through the liquid. Zinc can be separated in the same manner from iron, more free formic acid being used and the volume of the liquid increased. The precipitation of zinc in a citric solution presents no advantage, the precipitate being exceedingly difficult to filter and to wash. Bragard has further examined Tamm's determination of zinc as ammonio-phosphate (*CHEMICAL NEWS*, xxiv., 148). He finds this method most successful if 0.2 to 0.4 zinc is contained in 400 c.c. solution, and if the precipitate is allowed to stand for twenty-four hours. To prevent the precipitate from running through the washing-water should have at first the same temperature as the filtrate, and should be made hotter by degrees. He endeavoured to weigh the precipitate as pyrophosphate. He finds that a volatilisation of zinc may be avoided if the precipitate is heated alone, at first with a small flame, gradually made stronger so as to exclude the reducing action of the flame gases. Very strong heating should be avoided. To prevent the reductive action of the carbon from the filter, the precipitate is filtered in the smallest possible filter, from which it is carefully separated when dry. The paper is then carefully burnt separately after being moistened with ammonium nitrate. Zinc may be separated from magnesia by precipitation with sodium phosphate and excess of ammonia, provided the quantity of magnesia is not too large. Manganese can be separated in this manner from zinc only if in small proportion. —(*Chem. Zeitung*).

Determination of Cadmium and its Separation from Copper.—A. Kœhner.—This paper will be inserted at some length.

A Characteristic Reaction of Secondary Alcohols.—G. Chancel.—Already noticed under *Comptes Rendus*.

Volumetric Determination of Phosphoric Acid by Means of Uranium Nitrate.—Charles Malot.—Uranium nitrate forms a lake with the colouring-matter of cochineal; the author uses this result to indicate the end of the reaction in determining phosphoric acid. When the preliminary operations have been carried so far that the ammonium-magnesium phosphate exists dissolved in dilute nitric acid, some drops of an aqueous solution of cochineal are added, and then so much dilute ammonia that the colour appears just violet. This colour is then again removed by one or two drops of nitric acid. The liquid is now heated to 100° and mixed with 5 c.c. of a solution of sodium acetate, and the solution of uranium nitrate is then dropped in with a burette. Each drop, on falling, produces a greenish blue colour, which disappears again on stirring, until the last drop turns the whole mass of the fluid a permanent green. No uranium can then be detected in the solution. The reaction is, therefore, very distinct, and permits of the determination of phosphoric acid in great dilution.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Molybdic Acid.—I should be very much obliged if any reader of the CHEMICAL NEWS could give me any details of the manufacture of molybdic acid and molybdates commercially.—H. B. Stocks, 58, Nuttall Street, Liverpool.

ERRATUM.—P. 63, col. 2, line 16 from bottom, for "not only of this but any method in which the sulphur," read "not only of this but any method, the one in which the sulphur."

BRITISH ASSOCIATION for the ADVANCEMENT OF SCIENCE, 22, Albemarle Street, London, W.

The NEXT ANNUAL GENERAL MEETING will be held at BATH, commencing on WEDNESDAY, SEPTEMBER 5.

President Elect,
SIR FREDERICK J. BRAMWELL, D.C.L., F.R.S., M.Inst.C.E.
NOTICE TO CONTRIBUTORS OF MEMOIRS.—Authors are requested to give early Notice of their intention to offer papers. Information about Lodgings and other Local arrangements may be obtained from the Local Secretaries, 13, Old Bond Street, Bath.
A. T. ATCHISON, Secretary.

CITY AND GUILDS OF LONDON INSTITUTE. TECHNICAL COLLEGE, FINSBURY. S. P. THOMPSON, Principal.

DAY DEPARTMENT FOR STUDENTS NOT UNDER 14 YEARS of age.
The College Courses of Instruction in Laboratory, Lecture-Room, Workshop, and Drawing Office, for Mechanical Engineers, Electrical Engineers, and Technical Chemists, COMMENCE on TUESDAY, OCTOBER 2nd.

Chemical Laboratories, specially organised for Instruction in Technical Manufacturing Processes. Fee for Session, inclusive of Laboratories, Workshops, and Drawing Office, £9.
The Entrance Examination will take place on Wednesday, September 26th, at Ten o'clock a.m.

Scholarships of £30 a year each, and the Holl Scholarship of £20 a year, all tenable for two years, will be awarded (in accordance with the several schemes) on the results of the Entrance Examination.

For particulars of Scholarships and programmes of Instruction apply at the Technical College, Leonard Street, City Road, E.C., or at Gresham College, E.C.

JOHN WATNEY, }

IMPORTERS AND MERCHANTS,
Manufacturers of Mica Goods for Philosophical and ALL purposes.
Contractors to Her Majesty's Government.

The London Hospital and Medical College, MILE END, E.

The SESSION 1888-89 will commence on Monday, October 1st, 1888. The new buildings which were opened by T.R.H. the Prince and Princess of Wales, on May 21st, 1887, afford more than double the accommodation which was provided formerly.

Four Entrance Scholarships, value £60, £40, £30, and £20, will be offered for competition at the end of September to new students. Fees for lectures and hospital practice, 90 guineas in one payment, or 100 guineas in three instalments. All resident and other hospital appointments are free, and the holders of all the resident appointments are provided with rooms and board entirely free of expense. The resident appointments consist of five house physicians, five house surgeons, one accouchement, and one receiving-room officer; one senior dresser to out patients, dressers and maternity pupils also reside in the Hospital. Special classes for the preliminary scientific and Intermediate M.B. Examinations of the University of London and for the Primary and Pass Examinations for the Fellowship of the Royal College of Surgeons of England are held throughout the year. Special entries may be made for medical and surgical practice. The London Hospital is now in direct communication by rail and tram with all parts of the metropolis, and the Metropolitan, Metropolitan District, East London, and South Eastern Railways have stations within a minute's walk of the Hospital and College.

For prospectus and particulars apply, personally or by letter, to
MUNRO SCOTT, Warden.

CAUTION AS TO TRADE-MARKS.

CROWN CHEMICAL WORKS,
(Established 1863.) Marshgate Lane, Stratford, E.

NOTICE IS HEREBY GIVEN, That all Chemicals manufactured by us bear our Registered Trade-mark—

CROWN BRAND,

which is, as heretofore for the last quarter of a century, a guarantee in the markets of the world of the excellence of quality of our Sulphur, Acetic and other Organic Acids, Mineral Acids, and general Pharmaceutical Products.

A Special Quality of Sulphur manufactured by us is also guaranteed by our Trade-mark—

VELVET SULPHUR.

NOTICE IS ALSO GIVEN, That we are carrying on the business formerly carried on under the name of SCOTT and Co., at the CROWN CHEMICAL WORKS, by our Mr. JAMES EDWARD JOHNSON in partnership with others; and that an Interim Injunction was granted on the 22nd day of June, 1888, by Mr. Justice Stirling, in an Action of "Kindersley and Johnson v. W. T. Scott," restraining the Defendant from representing that he is carrying on the business of SCOTT and Co. or is in any way connected with such business; and by a further Order, made the 6th day of July, 1888, the Registration of the Trade-mark "Velvet Sulphur," as improperly obtained by the said Defendant, was ordered to be impugned.

NOTICE IS FURTHER GIVEN, That Proceedings will be taken against all persons infringing the above or any other of our well-known Trade-marks.

JAS. EDW. JOHNSON JOHNSON,
JAMES HOOPER,
Trading as KINDERSLEY and JOHNSON,
CROWN CHEMICAL WORKS,
Stratford.

Marylebone St.,
Portland Place, London

WILLIAM FOX, ANALYTICAL CHEMIST,
LABORATORY:
4, GREAT TOWER STREET, LONDON. E.C.
Analyses of Oils, Pigments, Varnishes, &c.

WEGELIN AND HÜBNER, Halle-on-Saale, MACHINE WORKS AND IRON FOUNDRY.

Representatives: NICKELS & Co., 150, Holborn, London, E.C.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37,746,
with increased effect through abolishing the noxious spaces; best
Air-Pump for Compression and Evacuation; useful effect up to 90
per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment,
with Attachment for Filtration with Exclusion of Air; in Wood,
Iron, or Bronze every desired size

Experimental Filter Presses in Wood, Iron or Bronze.

Filtration Experiments, if desired, carefully conducted in
our Laboratory).

Steam Pumps & Transmission Pumps,
horizontal, vertical, mounted on column, Wall Pumps, Pumps for
Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids.
"Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or
Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids,
any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof,
i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c.
Also Small Ice Machines for Families, Laboratories,
Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure
or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Com-
pound Steam Engines.
From 2—150 horse-power

Steam Water Pumps,

newest, most approved Construction, taking up little room, and
especially suitable for placing in Wells, with great efficiency; up
to largest sizes.

Compressors driven by Steam or Belt,
for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon,
Ether, Alcohol, Acetone, Water; In Iron or Copper. (Extraction
Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.
Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans,
and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin
Refineries, Resin Distilleries, Paraffin Works, Tar Dis-
tilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest
References for our above-named Specialities on
Application.

PATENT

THERMOMETERS AND PYROMETERS,

For indicating continuously
or occasionally all ranges
of temperature met
with in practice.

FOR USE IN CHEMICAL WORKS,
OIL WORKS, SUGAR REFINERIES,
IRON AND STEEL WORKS, ETC.

PRICES AND PARTICULARS
on application to

MURRIE'S ENGINEERING CO.,
45, WEST NILE STREET
GLASGOW.

SOLE MAKERS OF THE
MURRIE PATENT STEAM TRAP, LOW-WATER
ALARM AND BOILER FEEDER.

FILTER PRESSES

AND

MONSTRE FILTER-PRESSES

IN WOOD, IRON, BRONZE, AND LEAD.

In all sizes and for all purposes known.

CURIOUS ASSOCIATION OF HYDROCARBONS WITH ROCK-SALT IN NATURE.

By F. MAXWELL LYTE, F.C.S.

THE requent association of salt and bitumen or petroleum in the same deposits has often struck me as likely to lead to the development of some probable theory as to the formation of these hydrocarbons. Almost all specimens of rock-salt, when struck or rubbed, give off more or less the characteristic odour of bitumen. Beds of rock-salt are often coloured brown by the bitumen they contain, and petroleum, on its emergence, is nearly always associated with brine. Deposits of rock-salt are, as a rule, dry and anhydrous, though salt itself has a considerable attraction for moisture. But more than this, those salts of potassium and magnesium often occurring with it are still more greedy of water.

If the seemingly probable theory that all formations of rock-salt are due to the evaporation of sea-water be correct, then these deliquescent and hygrometric chlorides would almost always have been the last part deposited in every bed of rock-salt, and though, owing to their great solubility, they may have been denuded and washed or melted away perhaps long afterwards, it is probable that they generally formed the final layer at first. These would, by their affinity for water, both during their formation and subsequently, tend to withdraw that liquid from all surrounding substances.

Now most organic matter may be looked upon as a hydrocarbon combined with the elements of water. Withdraw the water and the hydrocarbon remains. Metallic iron, if present, might modify the reaction. Is it not, then, a probable theory that most natural deposits of hydrocarbons owe their origin to this absorption of water, acting through the lapse of ages on organic matter, often aided by heat and pressure? If such be admitted it would account for the frequent association of salt with hydrocarbons.

DISSOCIATION IN FUSED METALLIC SULPHIDES.

By T. STERRY HUNT.

In a note in the CHEMICAL NEWS, vol. lv., p. 3, Mr. T. Moore has described the formation, in a nickel matte or regulus, during its slow cooling, of brilliant crystalline plates, malleable and ductile, of metallic nickel, alloyed in different samples with from 12 to 28 per cent of iron, and amounting, in some cases, to one-tenth of the mass. A regulus containing Ni 73.8, Fe 4.2, S 22.0, in which the ratio S : M = 1 : 1.9; after yielding a portion of an alloy of Ni 86.4, Fe 13.6 gave the ratio 1 : 1.6 nearly, as calculated from Moore's analyses.

This process is not without precedent, since I published, in 1873, with details, the evidence of the separation of metallic iron from a copper-iron matte, with the further fact that the fused mixture was an oxysulphide, and was dissociated, on cooling, into an aggregate of metallic iron, magnetite, and sulphides. In commenting upon this fact in the second edition of my "New Basis for Chemistry" (Boston, 1888), p. 164, it is noted that the separation of filamentous copper (the so-called moss copper) during the cooling of rich copper regulus, is evidence of a similar dissociation of a sulphide, instable save at high tempera-

tures. I transcribe the foot-note given on the page just cited.

"A matte got from the first fusion of a roasted cupriferos pyrites held 45 per cent of copper, with a little zinc, and was strongly magnetic. Oxidised by nitric acid or by bromine, it left more than 10 per cent of pure magnetic oxide of iron. It, moreover, precipitated metallic copper and lead freely from solutions of these metals, and gave up to dilute acids the larger part of its iron, with evolution of free hydrogen and hydrogen sulphide gases, the latter apparently formed by the action of nascent hydrogen upon the metallic sulphide; from all which facts it was regarded as an intimate mixture of metallic iron, magnetite, and sulphides."—(*Trans. Amer. Assoc. Adv. Science*, 1873, p. 143).

Mention should here be made of the remarkable sub-sulphide found crystallised in cavities in the hearth in smelting for nickel matte in Pennsylvania, lately described by J. B. Mackintosh (*Trans. American Institute of Mining Engineers*, 1887). He found for brilliant cubical crystals the ratio S : M = 1 : 6, and the formula Fe_4Ni_2S ; two previous analyses of another specimen by Voigt having given similar results. It may be said that the sulphurous cast-irons offer us still more basic compounds of iron with sulphur.

London, August 10, 1888.

ON THE

PRESENCE OF FUSEL OIL IN BEER.*

By WILLIAM M. HAMLET, F.C.S., Government Analyst.

(Concluded from p. 83).

ANOTHER method for the estimation of minute quantities of amylic alcohol, and indeed for all the higher alcohols, is that of Traube,† who employs a method based on the fact that butylic and amylic alcohols depress the capillarity column in a small tube. This process has in my hands been found more suitable for brandies and white spirits than for beer.

During the first experiments in working out this process, a somewhat unlooked for result was obtained; one giving positive indications that genuine hops had been used in the brewing of all the samples of Sydney beer; thus corroborating the results I obtained by the methods of Dupré and Allen used in my search for spurious bitters and hop-substitutes.

Hops contain about $\frac{7}{12}$ parts in a thousand of an essential oil. This oil consists of a terpene isomeric with turpentine oil ($C_{10}H_{16}$) and a stearoptene termed valerol ($C_6H_{10}O$?) : the first, being a very volatile etherial body, is entirely dissipated during the process of brewing, and gives that pleasant aromatic odour often noticed in the brewery; the second consists of a mixture of the stearoptene valerol and resin. The valerol is easily oxidised by ordinary atmospheric oxidation into valeric acid, which may sometimes be observed in the peculiar cheesy smell of old hops.

Valerol being soluble in ether and in ethylic alcohol would therefore be found in the crude chloroform extract; hence the necessity for a prolonged washing with water to remove both the valerol as well as the ethylic alcohol before proceeding further with the process. If the impure and unwashed chloroform be oxidised the valerol would become oxidised into valeric acid along with the amylic alcohol. The presence of the hop oil of the hops may therefore be recognised if the chloroform residue be divided into two parts; one of which is thoroughly washed and oxidised by chromate. If oxidation yields valeric acid in the one case and none in the other, then it follows, and I think proves conclusively, that hops have been used in brewing the beer.

* Read before the Royal Society of N.S.W., November 2, 1887.

† *Bulletin de la Société chimique de Paris*.

The process, therefore has a double value and significance; namely, in determining first, whether the beer has been really flavoured with hops, and secondly, if the higher alcohols are present.

To remove all doubt as to whether the fusel oil really existed in beer, I took two litres of beer and removed the whole of the ethylic alcohol by slow and careful evaporation; the liquid was made alkaline by sodium hydroxide treated with ether in a separator and the valerol thus removed. Acetic acid was then added to neutralise the soda and the chloroform process, as before described and carried out. The result was that barium valerianate was produced as before. This was dissolved in water with a few drops of nitric acid, the barium estimated as sulphate, and the amount of fusel oil found and expressed in terms of amylic alcohol.

Four and a half litres of beer (=1 gallon) gave 0.530 grain of barium sulphate, equal to 0.4 grain of amylic alcohol per gallon.

One gallon of another sample gave on analysis 0.324 grain of barium sulphate, equal to 0.245 grain of amylic alcohol per gallon.

In another instance one gallon of a beer gave 1.18 grain of barium sulphate, equal to 0.89 grain of amylic alcohol per gallon, this being the largest proportion found. The amount therefore of fusel oil ranged from $\frac{1}{4}$ grain to nearly 1 grain [0.245 to 0.89] per gallon.

Molecular weight of $C_5H_{11}HO = 88$

ditto $C_5H_9O_2H = 102$

Molecular weight of $(C_5H_9O_2)^*Ba + 2OH_2 = 375$

1 part of ditto = 0.544 $C_5H_{11}HO$

1 part of $BaSO_3 = 0.7553 C_5H_{11}HO$

In the case of Marquardt's process for brandies and whiskies:—

1 part of $(C_5H_9O_2)^*Ba$ contains 0.4513 BaO ;

Whereas—

1 part of $(C_4H_5O)_2Ba$ contains 0.674 BaO .

Fusel oil or fousel oil, Fr. *Huile de pommes de terre*, Ger. *fuselöl*, derived from the Greek $\phi\omega$, I produce, alluding to its production or generation in and during the act of distillation and not merely to its eduction or mere separation from a liquid in which it is already present. I may say that I have very strong grounds for saying that it is not so, and that fusel oil is not a mere creature of the distilling process; but that it existed in the wash before distillation took place. However that may be, I will give a short description of what fusel oil is, and would refer my hearers to the many published accounts of this liquid.

The compound known as fusel oil is a complex oily liquid possessing a powerful sickly odour, producing nausea, coughing, irritation, and headache when inhaled, and having a biting fiery taste. It occurs in the residues, the faints,* of the distillation or rectification of all kinds of spirit, such as cane spirit, brandy, potato, rye, maize, and other grain spirit, from the marc of grapes and from the fermentation of sugar and glucose.

I desire it to be stated that I am not the first discoverer of fusel oil in beer, and that a paper appeared in the *Comptes Rendus*, xcvi., [19] 1368—1370, by J. A. Le Bel, who shows that amylic alcohol† is a product of the fermentation of beer. It has also been shown in Germany that when impure saccharum was used in brewing, that fusel oil was developed. In the *Rep. Anal. Chem.*, v., 188, a case is cited where a brewer was fined for allowing fusel oil to appear in his beer, and where it is stated that the fusel oil "may under certain circumstances prove injurious to health."

Toxic Action of Fusel Oil.

The administration of a quantity estimated at not more than $\frac{1}{4}$ grain kills frogs. One minim sufficed to kill three blow-flies. One minim killed a minnow. Two minims was fatal to guinea pigs. Sixty grains of fusel oil was

given to a dog. The effect was instantaneous, producing muscular paralysis of the hinder legs, with drunkenness, giddiness, and stupor. In a few minutes the animal was quite unable to stand on its legs and rolled about on the floor. In ten minutes the muscular tremors came on, recurring with perfect regularity. In twenty minutes there was foaming at the mouth. In thirty minutes the muscular tremors came on in paroxysms, especially at each inspiration of the lungs, amounting to what Dr. Ashburton Thompson better described as a spasm. The tremors continued for some time. In three hours the dog was in a state of coma, the twitching going on all the while regularly. At this stage violent headache and nausea was experienced by myself and two other observers. The dog was seized with a most violent fit of vomiting about five hours after, and partially recovered in 24 hours from the time of administration.

In conclusion, these results may be summarised as follows:—

1. That traces of certain other alcohols besides ordinary ethylic alcohol exist in most of the beers brewed in Sydney.

2. That these may be derived either from the temperature at which the fermentation is allowed to take place; or from the excessive use of saccharum, glucose, or sugar crystals, or from both.

3. That the presence of even traces of fusel oil is quite undesirable and most probably injurious to health, since it is known that small quantities of fusel oil act as a poison on the animal system.

DISCUSSION.

Mr. W. A. DIXON, F.C.S., said that it seemed to him that too much attention had of late been given to minute analysis of foods. Since Mr. Hamlet's first report had been published he had given a good deal of attention to this matter and had himself carried out some experiments. From these, as far as he had gone, he concluded that the glycerin formed during fermentation was extracted by the chloroform, and in the process used by Mr. Hamlet this was oxidised to formic acid and determined as valerianic acid and hence as amylic alcohol. Mr. Hamlet appeared to have only examined beers manufactured in Sydney. He (Mr. Dixon) had examined beer brewed at home, and found as much amylic alcohol as in any beer brewed here. It seemed to him that amylic alcohol was always produced more or less in fermentation; and that its production was not well understood. It is only known that it is produced in largest quantity from roots, next from raw grain, and generally when the yeast was in bad condition, and the temperature high. He did not think the temperature of fermentation here was carried much higher than at home, not much beyond 76 or 78° F., at the outside. If much amylic alcohol was produced the beer would be very distasteful. What was essential at one time was not so at another; thus, at one time beer was brewed without hops at all; in the reign of Queen Elizabeth very stringent regulations were laid down against the use of hops in beer, but the use of hops has so grown that the use of beer without is now almost unknown. Beer was a complex liquid containing various ingredients which made it palatable; some of them affected the sense of taste and others the sense of smell; these were called saps and odours, and together flavour. The bitter of hops and the salt affected the taste; some people liked more of the latter, some less, but the quantity present could scarcely produce thirst. The ingredients which affected the organs of smell were the oil of hops and the small quantities of those higher alcohols which were present, and if these were left out the beer would be undrinkable. What Mr. Hamlet has said with regard to the water here being particularly soft, and therefore taking up a large quantity of albuminous matter, was perfectly correct, and the brewer got rid of that difficulty by the use of sugar, as otherwise the beer would never be bright. The waters used in the brewing of some of the

* Faints contain over 60 per cent amylic alcohol.

† Named amylic alcohol by Cahours, from *amylum* starch.

English beers contained, besides the sulphate of calcium mentioned, sulphate of potassium, and both these were absent in Sydney waters. British beers contained from 200 to 300 grains of inorganic matter per gallon, which was more than in Sydney beer. With regard to the intoxicating effects of amylic alcohol, he did not think much dependence would be placed upon experiments made on animals. The effect of experiments made on different men might be very different, and the difference might be still greater between experiments made upon a man and a dog. For example, give a glass of rum to a black-fellow and he would be hopelessly drunk, but on most white men it would have no effect one way or the other. Various people had given different accounts of the effects of amylic alcohol; some said that it was fifteen times as intoxicating as ordinary alcohol; others said three grains produced decided effects. He knew of a case in which a man took a jar of fusel oil, thinking it was brandy, and took a mouthful of it; it made him drunk, but he soon got over it. Even if beer contained one grain of fusel oil per gallon, he did not think that was sufficient to condemn it, but he had not found nearly as much. As a chemist, he thought that too much importance was often attached to minute chemical analysis, and in a general way he considered that what would pass his sense of taste and smell was good enough.

The Rev. S. WILKINSON said he had been enabled to make some observations of the evil effects of fusel oil. There was one part of this colony in which wine was very extensively produced, and to his certain knowledge considerable quantities of very coarse sugar was used in fermentation in order to produce the wine; that he knew to be a fact, and it was a certainty from that fact that a considerable quantity of fusel oil is generated by fermentation to produce the wine he alluded to. But what was the result of it? He had been talking to a very trustworthy man in the police of that district, who had large experience of the men who had got drunk upon that wine, and his answer was, "Sir, they are not drunk, they are mad." He observed the difference between the men who got drunk on spirits and those who got drunk on the wine produced largely by the use of sugar, and these latter became perfectly mad with it. He was fully persuaded in his own mind that the larger the quantity of fusel oil found in beer or elsewhere the more deleterious were the effects, and therefore he thought that the results arrived at by our Government Analyst, after skilful examination, were most important, and showed that this oil was to be avoided by every possible means. He had not drunk any beer for a quarter of a century, but had observed the effects upon others. He was very pleased that Mr. Hamlet had not discovered any of those deleterious ingredients that are put in some of the beers in other countries, such as grains of paradise, *Cocculus indicus*, copperas, and other baneful metallic substances.

Mr. SMITH said the point seemed to have been lost sight of as to the amount of amylic alcohol necessary to produce any toxic effects. The authorities of the present day give 0.3 of a grain as the quantity required to produce toxic effects on the human system. Mr. Hamlet had shown that colonial beer contained, on an average, 0.05 grain to the gallon; therefore, to get enough amylic alcohol to produce any poisonous symptoms, a man must drink six gallons before it would produce any effect. It had been suggested that it might remain in the system over a period of time, and eventually the amylic alcohol produced toxic effects upon the system. Delirium tremens had been attributed to fusel oil, but was in no way caused by it. Mr. Dixon had spoken about the analysis of foods, and had rather cried down the analysing of food substances. With all due deference to Mr. Dixon he thought the paper read that night proved that there was a use in analysing food substances. Again, Mr. Dixon had made the remark that anything which would pass his nose and palate he thought good enough to take. He (Mr. Smith), while in England studying chemistry, on one occasion had been

appointed to go over one of the works where potted meat^s were largely manufactured. The course of inquiry was^s with reference to poisonous salts found in the meat, and this necessitated going through the whole process, and during the examination of the manufactory he certainly saw some things which had entirely prevented him, for some years past, from eating potted meats. The filthy way in which the meats were prepared would prevent many of the members here present from eating them again; it was only by analysis that we could find out and put a stop to unhealthy products being put on the market. Again, from a medical point of view, there were many diseases which could not be found out either by nose or palate; there are various species of tape-worm that cannot be found out by chemistry, but they can by microscopical examination.

Mr. W. A. DIXON wished to refer to the incident mentioned by Mr. Wilkinson, where men had been reported to be mad by the policeman as the result of drinking certain wine. He (Mr. Dixon) wished to point out that the effect of fusel oil in those cases in which it had been administered had been to produce coma and not madness. A man would be reported dead drunk, but would not be reported mad by the average policeman if the effect were due to fusel oil. As for potted meats, they never passed his palate.

The CHAIRMAN said he was perfectly aware that many ingredients were put in foods, although with no intent to cause injury; he was very glad to find that the samples of beer examined by Mr. Hamlet did not contain those injurious things which had been alleged. He certainly thought, from what he knew of the brewers here, they would not put in deleterious things; he felt assured that it was not the brewers, but the people through whose hands it passed afterwards, who adulterated the beer. Chemical analysis was very valuable, and Mr. Hamlet's investigations proved that fusel oil was there, although not in large quantities; but can it be produced without fusel oil? (Mr. Hamlet: Yes, it can). He was very pleased, and had been instructed by what he had heard that night, and wished that more of their members would come forward with papers. Before sitting down he would mention a fact that just occurred to his mind through reference to hops, and it was this:—That nearly all plants twine from right to left, but the hop is an exception; it twines the reverse way, and it was the only plant he knew that did so. He would tender, on behalf of the Society, a cordial vote of thanks to Mr. Hamlet for his paper.

Mr. HAMLET, in acknowledging the vote of thanks, said that he considered that anyone who had an interest in the State as a citizen should do all he could to investigate such matters rightly. He did not bring forward his paper to "rob a poor man of his beer," as the popular saying goes, but he simply stated what he found to be the fact—that fusel oil was contained in beer. He concurred very much in what Mr. Dixon had stated about the residues in British beers being higher than that in Sydney beer. He did not think that adding salt had any great deleterious effect, nor did he think the amount of common salt that Mr. Dixon referred to had any great effect, having regard to the fact that most people took a considerable quantity of salt in twenty-four hours. It had been remarked that a man must take a large quantity of beer before the fusel oil takes any effect. That might be so, but it was not so much that as the cumulative effect of amylic alcohol. If he were going to be dosed with minute doses for six months, it would accumulate in his system much in the same way as small doses of lead. If you took small doses of lead it would not produce any immediate effect; but, not being eliminated, it would be stored up in the body, and by-and-bye produce very alarming results, and it was quite possible that the toxic action of fusel oil would act much in the same way. The men about the streets were not to be compared with the ordinary drinker, who takes an occasional glass; those poor creatures that we saw standing about the corners of the streets were imbibing it

all day. They are members of the State, and we had, it was to be hoped, some degree of interest in mankind, so as to enable them to get as pure an article as possible. Mr. Dixon had suggested that he should have tried experiments on men and not on animals; that had been a great difficulty with him. He should like very much to have experimented on human subjects, and he had hinted as much, but of course it was an impossibility. He only knew, from these effects upon himself, that it was a very irritating disagreeable noxious liquid. With regard to the incident mentioned by Mr. Dixon of the man who took a gulp of fusel oil, he could only think it must have been largely diluted. The latest authorities on the subject considered that 1-60th to 1-15th of a grain produced intoxicating results. The effect on animals was very distressing to see.

In reply to a question of Dr. Leibius, Mr. HAMLET said there were no recorded experiments of the cumulative effects of fusel oil, but it was inferred from the innate properties of fusel oil that it was so. Of course, he did not compare it with lead, but merely mentioned lead by way of illustration, and it would not be fair to compare it with lead.—*Journal and Proceedings of the Royal Society of New South Wales*, Vol. xxi., Part 3.

A PROCESS FOR SEPARATING AND DETERMINING ZINC.

By J. RIBAN.

THE accurate determination of zinc in the moist way presents, as it is well known, great difficulties. The precipitation by means of ammonium hydrosulphate requires a settlement of from twelve to twenty-four hours; the filtration is discouragingly tedious, and we are compelled to load the mother-liquid and the washing waters with ammoniacal salts to prevent the precipitate from passing through the filter.

If we effect the precipitation in an acetic solution by means of sulphuretted hydrogen the sulphide obtained is still gelatinous, and presents similar inconveniences, though in a less degree. The precipitation of zinc by means of sodium carbonate is often incomplete, and the flocculent precipitate carries down considerable quantities of alkali, which cannot be completely eliminated by washing. Moreover, this method cannot be applied in presence of the alkaline-earthly bases, and only permits the separation of zinc from the alkalies.

The author has arrived at a process which is free from these defects. It consists in transforming the zinc salt into a soluble hyposulphate by the addition of an alkaline or earthy hyposulphate and treating it *in the cold* with sulphuretted hydrogen. There is formed a pure amorphous zinc sulphide, so dense that it soon collects at the bottom of the liquid, whilst the supernatant liquid remains clear, notwithstanding the movement produced by the gaseous current. As this precipitate is formed dithionic acid is set free, but its action upon zinc sulphide is very slight, and even null in dilute solutions, so that at certain degrees of dilution the process is at once expeditious and very accurate. The precipitate may be separated from the supernatant liquid by simple decantation, and can then be easily washed by continued decantation and filtration. The liquid containing the salt of zinc is saturated with sodium carbonate until a permanent precipitate appears, and is then re-dissolved by a few drops of dilute hydrochloric acid. To this slightly acid liquid there is added an excess of sodium or barium hyposulphate, more than sufficient to effect the double decomposition with the salt of zinc and the free acid; an excess of the hyposulphate does no harm. The liquid is diluted with water so that it may contain, at most, 0.1 grm. zinc in 100 c.c. There is then passed into it a current of sulphuretted hydrogen in the cold. The precipitate of zinc

sulphide, quite white and very heavy, collects quickly. After letting settle for a few minutes the limpid liquid is decanted carefully through a filter. Upon the precipitate is poured boiling water and sulphuretted hydrogen water, when the precipitate soon settles again. After two or three such washings by a decantation through a filter the washing is completed in the filter, always with hot water mixed with sulphuretted hydrogen water. It is dried at 100°, separated as completely as possible from the filter, which is incinerated in a porcelain crucible, after moistening the paper with ammonium nitrate. Lastly there is added to the ash the zinc sulphide and free sulphur, and the whole is ignited in a current of hydrogen according to Rose's process. Or the sulphide may be converted into oxide by roasting.

This method allows of the separation of zinc from the alkaline-earthly and alkaline metals, using, for the latter, barium hyposulphate in place of the sodium salt.

As iron, manganese, &c., are not precipitated by sulphuretted hydrogen in presence of the hyposulphates, the zinc may be separated from these metals and determined without the previous elimination of iron.—*Comptes Rendus* (vol. cvii., p. 341).

NOTES ON ANALYTICAL METHODS.*

By Dr. T. B. OSBORNE.

Filtration of Crude Fibre.

THE filtrations in the process of determining crude fibre are commonly quite difficult and tedious, the acid liquids especially, either running turbid through a coarse filter or clogging a fine one. In most cases these troubles may be avoided by using the filter-pump and a paper filter supported on a platinum cone, and by breaking the filter down the fold or crease on one side. This is done by folding the paper so as to form a cone of an angle slightly less acute than the funnel, placing it in the latter, moistening, and then applying the suction, when the paper will usually tear apart, leaving a narrow rift from the vertex upward, across which stretches a loose network of fibres. If the sample has not been too finely ground it may be filtered clear by shaking or stirring up thoroughly, and throwing quickly on to the paper, so that the coarser particles will hold the finer and prevent the latter from passing the rift or clogging the paper. The break allows the solution to run off rapidly, so that in most cases but three or four minutes are necessary to conclude the filtration.

This method has given good results in crude fibre determinations with hay and bran-feed and with sheep-dung, which were very difficult to manage by the usual methods.

Filtration and Weighing of Silver Chloride.

Solutions containing organic matter are often very difficult to filter from silver chloride, this precipitate at first running through, and afterwards clogging the paper so as to make the filtration slow. The removal of the precipitate from the paper, and the conversion of the reduced silver obtained after burning into chloride again, are operations taking considerable care and time. In many cases it is better to allow the precipitate to settle and to decant the greater part of the liquid through a Gooch asbestos filter. The precipitate is then dissolved in a very slight excess of ammonia water, the concentrated solution being thereupon made slightly acid with nitric acid; the precipitate will separate in a floccy form, which, after carefully washing by decantation, may be thrown on to the filter and sucked dry with the pump without danger of running through. If the precipitate be fused it is somewhat difficult to remove from the crucible, but it may be

* From Report of the Connecticut Agricultural Experiment Station for 1887.

dried at 100°, at which temperature a constant weight is obtained in from a half to one hour.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING JULY 31ST, 1888.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolitan Water Act, 1871.

London, August 4th, 1888.

SIR,—We submit herewith the results of our analyses of the 182 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from July 1st to July 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

The London waters during the past month have continued to be of their usual excellent quality. A few samples of the East London Water Company's supply presented a slight turbidity, dependent on the exceptional circumstances explained in former reports.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

CONTRIBUTIONS TO A KNOWLEDGE OF THE RARE EARTHS WHICH PRODUCE ABSORPTION-SPECTRA.

By PAUL KIESEWETTER and GERHARD KRÜSS.

(Concluded from p. 76).

Gadolinite from Hitterö.

GADOLINITE, a mineral so often used as a source of rare earths, has not been as yet spectroscopically examined like euxenite, fergusonite, thorite, keilhauite, &c. Therefore 120 grms. of this mineral from Hitterö were most finely powdered, evaporated down several times on the water-bath in strong hydrochloric acid, and thus fully opened up with liberation of silica. The oxalates precipitated from the hydrochloric solution formed a deep yellow oxide, the solution of which in nitric acid was concentrated on the water-bath and heated for some time. After being taken up in a small quantity of water the solution was again heated for some time on the water-bath, repeating this process five times so as to give a perfectly neutral solution of the nitrates of the gadolinite earths. It gave the following spectrum:—

Gadolinite from Hitterö.

Observed position of maximum darkness.	Wave-length observed	Wave-length by Krüss and Nilson.	For.	Intensities of absorption-bands.
(Position of drum.	Wave-length observed.			
296	727·8	728·3	Dia	Rather strong.
398	690·7	690·5	Dic	Very faint.
419	683·7	684·0	Tma	Faint.
453	673·5	—	?	Very faint.
525	653·1	654·7	Era	{ Rather faint, identified with Era by comparison.
574	641·7	640·4	Xa	Faint.
733	605·5	—	?	Extremely faint.
788	592·9	591·5	Di	Extremely faint.
863	580·3	579·2	Diγ	Very strong.
895	575·3	575·4	Diγ	Strong.
1105	542·8	542·6	Xβ	Very faint.
1128	539·3	539·9	?	Faint > λ = 539·9.
1241	522·9	523·1	Erβ	Strong.
1257	520·9	521·5	Diδ	Rather strong.
1347	511·2	512·2	Die	Faint.
1589	485·9	485·5	Xδ	Rather strong.
1728	476·6	477·7	Smβ	Very faint.

2203	444·1	444·7	Diε	Scarce visible.
2453	428·2	428·5	Xη	Very faint.

In gadolinite there occur a considerably larger number of rare earths than in keilhauite. Noteworthy is the absence of Sma, and of Diε, Diη, and Diθ in the gadolinite material at the author's disposal, as well as the occurrence of Diκ for the nitrate of which the line λ = 690·5 could be observed in the spectrum. Diκ had been previously found by Krüss and Nilson only in the cerite of Bastnäs, and in no other of the minerals examined. The line λ = 539·9 was also observed which had been previously detected by Krüss and Nilson in the spectra of the holmium material, and that of the earths of the wöchlerite and thorite of Brevig, though it had not been identified with any line previously observed. Two lines were also observed at λ = 673·5 and λ = 605·5, but they could not be distinctly ascribed to any of the earths.

Above all it must be pointed out how unfavourable is the choice of gadolinite which has been so often employed for obtaining the erbium and didymium earths. The advantage of its relatively large proportion of yttrium earths can scarcely counterbalance the disadvantage of its great complexity unless better methods for the separation of the rare earths are discovered. As a proof the authors give the qualitative composition, as ascertained by spectroscopic examination of twelve principal fractions, into which the earths of gadolinite are resolved by fractionated decomposition of the nitrates according to their basicity. (See Table next page).

In all the fractions the nitrates of a whole series of earths are always simultaneously present, and gadolinite behaves like euxenite and fergusonite. Even in those fractions in which, among the earths producing absorption-spectra, only Tma and Era were present, or Tma alone, the colourless ytterbia was jointly present. If, therefore, we use, as was often attempted, gadolinite, euxenite, and other minerals containing a great number of rare earths, we shall succeed in isolating one or the other element only if we have at the outset a great weight of material, say 20—25 kilos. We shall effect our purpose more readily if we select as our starting-point a mineral containing a relatively small number of the rare earths. In the first place the earths of keilhauite will be worked up in quantity, and the isolation of Xε, Diδ, and Erβ attempted. — *Berichte der Deutsch. Chem. Gesellschaft*, vol. xxi., p. 2310.

BROMINE VERSUS CHLORINE FOR GOLD EXTRACTION.

By W. H. BURFEIND.

EVERYONE who has worked ores by the Plattner process and has studied its details will acknowledge its chemistry perfect, and that it gives excellent results if carefully manipulated on suitable material. However, excellent as it is, this "if" often proves a serious obstacle. The cost of the plant is large. Heavy, bulky, and perishable generators are necessary. The vats of a medium-sized plant cover a large area. The building containing them must be large. A good deal of expensive tubing is consumed. A large supply of sulphuric acid, manganese, and salt must be on hand. The former is very expensive where freights are high. Not only the operator, foreman, or superintendent, as he may be called, must thoroughly understand the process, but also the other help must be skilled and trustworthy. Every part of the manipulation must be carefully attended to, or the result will disgust the operator and prove a loss to the owner.

I will demonstrate my views by giving a method for assaying gold ores with bromine water. The chemistry of this method is exactly that given by Plattner. I simply employ bromine in place of chlorine as a solvent. The operation is as follows:—

Bromine Assay of Gold Ores.

Weigh out the material, more or less according to richness, roast, with or without salt if sulphides are present, put it in to any kind of a bottle which will hold about one-third more than the quantity to be treated (a one-half gallon acid bottle will answer well for three or four pounds material), then add bromine water of any strength so that it will stand an inch or two over the ore, cork the bottle and shake well for a short time, let stand about an hour, giving it an occasional shake. If the gold is not too coarse and there is by this time still free bromine in the bottle the solution is complete, otherwise more bromine water must be added and additional time given. Pour the contents of the bottle into a filter, wash thoroughly with cold water until the wash water is not any more darkened by a solution of ferrous sulphate, best seen in a porcelain evaporating dish. Treat the filtrate in the same manner as if chlorine gas had been used.

All that is necessary for this test is a bottle and bromine water; both are found in every laboratory. Gas generator with tubing and receiver are superfluous. The ore cannot be put in too wet or too dry; there is no danger of packing it too tight or uneven, but it can be put into the bottle promiscuously, wet or dry. By shaking it with the bromine water, every particle of it will come into contact with the bromine. The "occasional shake" offers a fresh, bright surface to the bromine, which saves time in all cases, but is of special benefit if the gold is alloyed with quite an amount of silver. (Being once in a hurry to determine the gold left in the tailings I simply shook a small amount of ore with bromine water for 10 minutes, filtered it off, and found only a trace just visible from a 150 dollar ore). No unpleasant gases fill the laboratory if the filtering is done under a hood. The presence of free bromine is as easily detected as that of free chlorine. It is also a sign that enough has been added. The operator, if working on one kind of material, will soon know the exact amount of bromine necessary.

The time consumed is less, results will agree to a nicety with the most carefully manipulated test made with chlorine gas; and what is best, skilful manipulations do not enter into any part of the process. It can, therefore, be executed by any assistant.

A good many of the above advantages are obtained if bromine water is used in place of chlorine gas on a large scale. A series of tests made on a large scale verified my conclusion; but I am not in a position to test this as fully as I would like.

The main objection to using bromine on a large scale, is the danger in shipping and handling large quantities of it, and, I may add, that this is the only one under a good many circumstances. I must confess that I am at a loss to overcome this last and main trouble. To ship it in the shape of bromides will not answer, as it destroys all the advantages offered. It has occurred to me that it might be possible that it can be shipped as nitro-glycerin in an absorbent. I have not at present the convenience to follow this up, and should be pleased to learn that parties interested in the manufacture of bromine have already discovered a suitable method. As soon as bromine can be handled and shipped without danger, it will be used very extensively in the Western mining region.—*Engineering and Mining Journal*.

GEOMETRICAL ILLUSTRATIONS OF
NEWLANDS' AND MENDELEEFF'S PERIODIC
LAW OF THE ATOMIC WEIGHTS OF THE
CHEMICAL ELEMENTS.*

By the Rev. SAMUEL HAUGHTON, M.D.

PART I.—THE FIRST AND SECOND PERIODS OF SEVEN
ELEMENTS FOLLOWING HYDROGEN; OR, THE CARBON-
SILICON DOUBLE PERIOD.

I ASSUME on the part of my readers a general knowledge of Newlands' "Law of Octaves," of Mendeleeff's "Periodic Law," and of Reynolds's graphic representation of the results arrived at by their successors on this remarkable subject.

I reproduce in Plate I., with Dr. Reynolds's permission, the most recent graphic representation of the "Periodic Law."

In this diagram the elements are plotted according to their atomic weights and valencies; the vertical co-ordinates being atomic weights and the horizontal co-ordinates being valencies, counted (for convenience of plotting) positive or negative, according as the element belongs to an odd or even period of seven.

First Period or Carbon Period.

Element.	Atomic Weight.	Valency.
1. Lithium	7	Monad.
2. Beryllium	9	Dyad.
3. Boron	11	Triad.
4. Carbon	12	Tetrad.
5. Nitrogen	14	Triad.
6. Oxygen	16	Dyad.
7. Fluorine	19	Monad.

Second Period or Silicon Period.

Element.	Atomic Weight.	Valency.
1. Sodium	23	Monad.
2. Magnesium	24	Dyad.
3. Aluminium	27	Triad.
4. Silicon	28	Tetrad.
5. Phosphorus	31	Triad.
6. Sulphur	32	Dyad.
7. Chlorine	35½	Monad.

In Plate II. I show on an enlarged scale Dr. Reynolds's diagram for the above-named Carbon and Silicon Periods following hydrogen. This diagram is formed by joining together by right lines the successive fourteen points, commencing with lithium and ending with chlorine. If the points were at random the number of right lines would be thirteen; and this would be the order of the curve passing through the fourteen points, and an infinite number of such curves could be drawn, and the problem would be geometrically indefinite. The points being supposed placed at random, it is well known that a single general quartic curve can be drawn through them, and one only, thus giving an unique geometrical solution.

A general quartic curve is therefore the simplest solution that the collocation of fourteen points admits of in its most difficult form; but this solution may become simpler if the points are arranged by a law or method and not at random.

In the problem now before us we find on inspection that five of the fourteen points lie on the same straight line,* viz. :—

This is shown in Plate III.

This line joins the two tetrads, carbon and silicon, and passes through the point 20 of the line of atomic weights.

There remain nine points not accounted for, viz :—

These nine points are found to lie upon a simple serpentine cubic with one real asymptote, which I have plotted in Plate III.

Taking the point 20 for origin, the co-ordinates of the nine points are as follows :—

	x.	y.
1. Lithium	-13	-1
2. Beryllium	-11	-2
3. Boron	-9	-3
4. Fluorine	-1	-1
5. Sodium	+3	+1
6. Aluminium	+7	+3
7. Phosphorus	+11	+3
8. Sulphur	+12	+2
9. Chlorine	+15½	+1

* Abstract of a Paper read before the Royal Irish Academy, April 28, 1888.

* The chances are millions to one against this happening at random.

lies altogether inside the tetrad line, and the same remark applies to the eleventh element, silicon.

In the remaining six elements lying between carbon and silicon, what (for want of a better word) I may call a "contest" takes place between the lineal branch and the cubic branch as to which of them shall have the element, but in no case are two elements formed with the same valency.

1. In the triad line nitrogen is formed on the lineal branch, but there is distinctly intimated the possibility of another element on the cubic branch with the atomic weight 13, where the cubic, having passed through boron, again intersects the triad line.

2. On the dyad line oxygen is formed on the lineal branch, but the possibility is shown of another element on the cubic branch with the atomic weight 16·4.

3. On the monad line fluorine is formed on the cubic branch with a possibility of another element on the lineal branch of atomic weight 18.

4. Again sodium is formed on the cubic branch with a possibility of an element on the lineal branch with atomic weight 22.

5. Magnesium is formed on the lineal branch with a possibility of another element on the cubic branch with atomic weight 25.

And lastly, aluminium appears on the cubic branch with a possibility of another element on the lineal branch of atomic weight 26.

These two periods of seven elements each form the first two octaves of the chemical harmony of the universe; but what are we to do with hydrogen, which remains alone outside the harmony?

Mendeleeff thought that his six missing brothers and sisters were to be sought between hydrogen and lithium; but Dr. Reynolds easily proved that they must be sought for behind hydrogen, which is the last note of the primeval octave. Are they to be found between zero and unity or looked for "behind the looking-glass" in the unknown land of negative atomicities, where heat, light, and electricity reside?

However this may be I think it useful to point out a remarkable relation between hydrogen and the fourteen elements which follow it in atomic weight.

If we take the common centre of gravity of the fourteen elements (regarded as equal weights) and join this point with the point representing hydrogen, the line so found is very nearly parallel to the asymptote of the cubic curve drawn in Plate III.

The difference in direction between the two lines is only 20' arc.

Hydrogen, the first born and king of the elements, sits alone without brothers or sisters, and seems to resemble the fabled Isis of Egyptian mythology—

Ἐγὼ εἰμι πᾶν τὸ γεγονός καὶ ὄν, καὶ ἐσόμενον, καὶ τὸν ἐμὸν πέπλον οὐδεὶς πω θνητὸς ἀπεκάλυψε.

CORRESPONDENCE.

ESTIMATION OF SULPHUR IN IRON AND STEEL.

To the Editor of the Chemical News.

SIR,—Referring to the correspondence now proceeding in your paper *re* "The Estimation of Sulphur in Iron and Steel," I cannot quite make out what Mr. Morgan purposes to show in his article (CHEMICAL NEWS, vol. lviii., p. 63), the processes therein detailed being old standing methods employed in every Steel Works Laboratory, and the errors he points out as liable to occur are such as no experienced chemist would be in danger of falling into. With care almost the exact moment can be judged when the acid solution shall be basic, and if evaporation is carried beyond this point the iron is immediately precipitated. The most important point to be watched in working the BaCl₂ process is, I find, the impurities in the reagents; the purest acids I have been able to procure contained 0·007 per cent sulphur, and many samples contain as high as 0·013 per cent, calculated on 5 grms. of steel, although sold as *Sulphur Free*.

With regard to Parry's colorimetric process, Mr. Morgan observes that with "practice" the precipitation of PbS may be avoided even in working on a steel containing as high as *over* 0·2 per cent sulphur (rather high sulphur that; we do not get them so high in Sheffield as a rule). Although I have had considerable practice, I always get a precipitate when estimating a steel containing 0·06 or over; while by the method published by Messrs. Arnold and Hardy I can get good and concordant results, their self-registering method working exceedingly regularly, and the time thereby saved where accurate results are indispensable is a great point gained over the BaCl₂ method, where to obtain an accurate result, especially in a very low sulphur steel, quite two days are required, not to mention trouble of manipulation. Mr. Morgan states it does not signify whether the H₂S is evolved rapidly or slowly. I have found quite the reverse to be the case: if the gas be evolved slowly precipitation is not so likely to take place as when it rushes off rapidly, thereby agitating the volume of solution contained in the cylinder. Mr. Morgan states he has difficulty in obtaining regular steels to use as standards. I think there would be some little difficulty in obtaining standards to meet the range he mentions, 0·02 to 0·2 and over. To meet this range, and to obtain an estimation of an unknown steel, about eight standards would have to be weighed out and dissolved, thus making nine weighings for a single result, whereas the method proposed by Messrs. Arnold and Hardy would meet the case in a single operation. Again, let Mr. Morgan work in an atmosphere of hydrogen, and he will find that he gets much more reliable results than when working in atmospheric air, where a portion of his H₂S is liable to be oxidised.—I am, &c.,

B. W. WINDER.

The Laboratory,
Bessemer Road, Attercliffe.

British Association for the Advancement of Science.—It is proposed by the Organising Committee of Section B that, in the course of the approaching meeting, there shall be a discussion in that Section upon the subject of "Valency." Professor Armstrong will open the debate, and it is hoped that several other eminent chemists will take part. In the immediate neighbourhood of Bath there are no industries especially interesting to chemists, but arrangements are in progress by which it is hoped that members will be admitted to some of the works in and about Bristol, which is only ten miles away.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 6, August 6, 1888.

New Experiments on the Fixation of Nitrogen by Certain Vegetable Soils and by Certain Plants.—M. Berthelot.—In all the cases which the author has observed, and with the earths taken for experiment, fixation of nitrogen has taken place, as well in vessels hermetically sealed as in soils merely covered, and in those fully exposed to the air, and in bare earth as well as in presence of leguminous plants. At the outset of the growth of the latter the absorption of nitrogen falls mainly upon the soil, but as the plant becomes vigorous it draws nitrogen from the soil, which then retains merely a fraction of the total gain. The author reserves for future study the question whether a part of the nitrogen gained by a vigorous plant is not in part taken directly from the atmosphere.

On Levulose.—M. Jungfleisch and L. Grimbert.—Leaving out of the question the influence of the time elapsed since the solution of levulose has been made, and also permanent modifications resulting from an alteration in the saccharine matter, the authors have made a number of experiments which have been summed up in the following formula, in which t represents the temperature, p the weight of levulose contained in 100 c.c. of liquid:—

$$\alpha_D = -101.38 - 0.56t + 0.108(p - 10).$$

This formula is applicable at temperatures from 0° to 40°, and at degrees of concentration less than 40 per cent.

Potassium and Sodium Malonates.—G. Massol.—A thermo-chemical paper, not adapted for useful abstraction.

On Methane and Ethylene Hydrates.—M. Villard.—Methane forms with water a crystalline combination which is destroyed only above 21.5°. The hydrate exists at temperatures much higher than the critical points of the gas, —99.5°. The crystals of ethylene hydrate are slowly destroyed at 18.7°, even under strong pressure, a temperature notably higher than the critical point of ethylene, +10.1°.

Observations on the Fixation of Atmospheric Nitrogen by Leguminous Plants whose Roots have Nodosities.—E. Bréal.—The author has studied these nodosities as obtained from acacias, peas, lupins, kidney beans, and lentils. On a microscopic examination of the nodosities he observed rounded, very refringent granules, mixed with "filaments in motion resembling bacteria." On analysis he found these nodosities decidedly richer in nitrogen than the stems and leaves of the same plants, the thick roots, or the root-fibres.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 2.

Methods of Separating and Determining Arsenic, Antimony, and Tin.—E. Lesser.—The author gives the preference to the process of F. W. Clarke (CHEMICAL NEWS), with the following precautions. The solution of the metals is neutralised, as far as possible, so as to admit of a complete precipitation of the antimony. So much oxalic acid is then added that it may be from 35 to 40 times the weight of the tin. The approximate quantity of tin is found by taking the sulphides thrown down by sulphuretted hydrogen from a distinct portion of the sample, oxidising with nitric acid, filtering off the insoluble residue of stannic oxide and antimony tetroxide, igniting in a tared crucible, and weighing. After the addition of oxalic acid the solution is heated, and sul-

phuretted hydrogen passed in to saturation, when the precipitate is filtered off. The metallic sulphides are dissolved in ammonium sulphide and, after acidulation with oxalic acid, again treated, hot, with sulphuretted hydrogen, in order to remove the small quantity of tin which was carried down in the first precipitation. The two filtrates containing the tin are mixed, concentrated, and precipitated according to Clarke's directions with ammonia, ammonium sulphide, and acetic acid, the precipitate being then determined in the ordinary manner as tin oxide. For separating the arsenic and antimony, the sulphides are dissolved off the filter into a beaker in warm ammonium sulphide and then oxidised with hydrochloric acid and potassium chlorate. The solution is mixed with tartaric acid and ammonia in excess, and the arsenic acid is precipitated with magnesia mixture. In order to remove basic magnesium tartrate from the precipitate, it is redissolved in hydrochloric acid, and, with the addition of a little magnesia mixture, once more precipitated with ammonia. The ammonium-magnesium arseniate is then weighed with the ordinary precautions. The filtrate is acidified, and the antimony precipitated with sulphuretted hydrogen; the antimony sulphide is converted into tetroxide and determined as such.

Studies on the Kjeldahl Process for Determining Nitrogen.—F. W. Dafert.—The bodies which are directly amenable to the Kjeldahl process are:—All amides and ammonium bases, the pyridin and chinolin bodies, the alkaloids, the bitter principles, the albumenoids, and kindred substances. The following bodies require previous preparation:—All nitro-, nitroso-, azo-, diazo-, hydrazo-, and amido-azo-compounds, the compounds of nitric and nitrous acid, the hydrazines, and probably the cyanides. For the nitro-compounds the author proceeds as follows:—The substance in question is dissolved in 10 c.c. of alcohol (or, if very resistant, at once in ordinary oil of vitriol), mixed with zinc powder, and heated with the addition of 10 c.c. of oil of vitriol until the alcohol is expelled. He then adds 10 c.c. of "acid mixture" (which is made up of 1 litre rectified monohydrated sulphuric acid and 200 grms. phosphoric anhydride) and mercury and proceeds in the ordinary manner. In distilling with soda-lye caution must be used, as the flasks are apt to burst in consequence of the dense coating of sulphide. It is best to heat upon the sand-bath with frequent shaking. Nitroso-derivatives may also be treated in this manner.

Determination of Sulphur and of the Halogens in Organic Bodies.—Peter Claesson.—The author conducts the combustion, not in a current of oxygen, but of common air, which he charges with the requisite nitrous vapours in the combustion tube. A single tube for the introduction of gases is sufficient, instead of the two currents shown in *Zeitschrift* (xxvi., p. 372, Fig. 40). The nitric acid is absorbed in four cylindrical cages of platinum wire, filled with small glass beads, and introduced into the combustion tube. They absorb about 8 c.c. of red fuming nitric acid. The combustion tube is charged exactly as in the author's earlier arrangements, but between the platinum wire cages 1 and 2, not containing nitric acid, then come two of the cylindric cages just mentioned; then, behind the boat, an ordinary platinum wire cage, and then, at a little distance, two cylindrical cages containing nitric acid. The two empty platinum cages situate at the drawn out end are first heated to redness; then, about 1 c.m. behind each nitric cage, a small flame is lighted, whilst a slow current of air is drawn through the combustion tube. When the tube is thus filled with nitrous vapours heat is applied to the substance proceeding in an opposite direction to the current of air. The contents of the tube between the acid cages nearest the point and the boat must always be red, otherwise the heat of the substance must be reduced or the current of nitric acid must be reinforced. The vapours issuing from the tube must always be red. Finally, the nitric acid remaining in the cages, and any sulphuric acid which may have been formed, are driven by heat into the

receiver, let cool, the cages are emptied out into a capsule, and rinsed with water. The washings and the water used in rinsing out the tube are added to the contents of the receiver, which are then treated as in the author's former memoir.

Contributions to a Knowledge of Hydrocyanic Acid and of Cyanogen Iodide.—E. von Meyer.—From the *Journal für Prakt. Chemie*.

Detection and Determination of Micro-organisms in the Air.—R. J. Petri.—The micro-organisms suspended in the air are filtered out in a sand-filter. The filter, charged with germs, is divided into convenient portions, placed in flat double capsules, and mixed with gelatin. The colonies which develop are counted, and in this manner the micro-organisms are estimated in the volume of sand examined. The sand used for the filters should have its granules of the size of 0.25 to 0.5 m.m., and must have been previously ignited. It is introduced into a glass tube 8 to 9 c.m. in length, in the state of two plugs supported by small wire nets, each plug being 3 c.m. long and from 1.5 to 1.8 wide. The two filters come in contact at the middle of the tube, both ends of which are firmly closed with plugs of cotton-wool. For the experiment these plugs are removed, and one end of the tube is connected by means of a lead tube with a sufficiently powerful filter-pump. The aperture of the filter through which the air enters is turned upwards. The quantity of air passed through the apparatus is determined by means of a gas-meter. Not more than 10 litres should be passed in one to two minutes, the speed of the air current in the sand not exceeding 0.7 metre per second. The sand charged with germs is preferably sown at once, though a delay of seven weeks does not seem to occasion any injury. It is sown in double capsules of 9 c.m. in diameter. The plug of sand first traversed by the air, which has taken up all the microbia from the volume of air, is distributed in a suitable number of such capsules and covered with liquid gelatin. The sand from the second plug should be free from germs.

Examination of Honey.—K. Kayser.—The residue from the fermentation of pure honey is, as a rule, optically inactive, and, if heated with hydrochloric acid, it contains only exceptionally traces of reductive sugar. Sieben's first two methods for the examination of honey should therefore be modified as follows:—25 grms. honey are mixed with 12 grms. solid yeast (free from starch), and made up with water to 200 c.c., and let ferment for forty-eight hours at a medium temperature. Aluminium hydroxide is then added and the mixture made up to 250 c.c.; 200 c.c. of the clear filtrate are concentrated to 50 c.c. and polarised in a 200 m.m. tube. A deflection of more than 1° (Wild) proves that starch sugar has been added. 25 c.c. of the liquid used for polarising are then mixed with 25 c.c. water and 5 c.c. strong hydrochloric acid and heated for an hour in a boiling water-bath, neutralised, made up to 100 c.c., and any sugar formed is determined by Allihn's method in one quarter of the liquid. The sugar thus found, multiplied by 40, gives the quantity of sugar which comes to the fermentation residue from 100 grms. of honey. If this exceeds one per cent starch sugar has been added.

Wanted, a Laboratory Assistant in a School for a few months. Some experience of teaching Elementary Chemistry desirable.—Address, "Lab.," 163, Finborough Road, South Kensington.

Wanted, Situation by Young Man (27), thorough Chemist, and Fellow of the Institute of Chemistry. Has had charge of men. Moderate salary. Good testimonials.—Address, C. J., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

ST. PAUL'S SCHOOL.—An Examination for filling up about Eighteen Vacancies on the Foundation will be held on the 12th September next.—For information apply to the Bursar, St. Paul's School, West Kensington.

The London Hospital and Medical College, MILE END, E.

The SESSION 1888-89 will commence on Monday, October 1st, 1888. The new buildings which were opened by T.R.H. the Prince and Princess of Wales, on May 21st, 1887, afford more than double the accommodation which was provided formerly.

Four Entrance Scholarships, value £50, £40, £30, and £20, will be offered for competition at the end of September to new students. Fees for lectures and hospital practice, 90 guineas in one payment, or 100 guineas in three instalments. All resident and other hospital appointments are free, and the holders of all the resident appointments are provided with rooms and board entirely free of expense. The resident appointments consist of five house physicians, five house surgeons, one accoucheurship, and one receiving-room officer; one senior dresser to out patients, dressers and maternity pupils also reside in the Hospital. Special classes for the preliminary scientific and Intermediate M.B. Examinations of the University of London and for the Primary and Pass Examinations for the Fellowship of the Royal College of Surgeons of England are held throughout the year. Special entries may be made for medical and surgical practice. The London Hospital is now in direct communication by rail and tram with all parts of the metropolis, and the Metropolitan, Metropolitan District, East London, and South Eastern Railways have stations within a minute's walk of the Hospital and College.

For prospectus and particulars apply, personally or by letter, to
MUNRO SCOTT, Warden.

CAUTION AS TO TRADE-MARKS.

(Established 1863.) CROWN CHEMICAL WORKS,
Marshgate Lane, Stratford, E.

NOTICE IS HEREBY GIVEN, That all Chemicals manufactured by us bear our Registered Trade-mark—

CROWN BRAND,

which is, as heretofore for the last quarter of a century, a guarantee in the markets of the world of the excellence of quality of our Sulphur, Acetic and other Organic Acids, Mineral Acids, and general Pharmaceutical Products.

A Special Quality of Sulphur manufactured by us is also guaranteed by our Trade-mark—

VELVET SULPHUR.

NOTICE IS ALSO GIVEN, That we are carrying on the business formerly carried on under the name of SCOTT and Co., at the CROWN CHEMICAL WORKS, by our Mr. JAMES EDWARD JOHNSON in partnership with others; and that an Interim Injunction was granted on the 22nd day of June, 1888, by Mr. Justice Stirling, in an Action of "Kindersley and Johnson v. W. T. Scott," restraining the Defendant from representing that he is carrying on the business of Scott and Co. or in any way connected with such business; and by a further Order, made the 6th day of July, 1888, the Registration of the Trade-mark "Velvet Sulphur" as improperly obtained by the said Defendant, was ordered to be expunged.

NOTICE IS FURTHER GIVEN, That Proceedings will be taken against all persons infringing the above or any other of our well-known Trade-marks.

JAS. EDW. JOHNSON JOHNSON,
JAMES HOOPER,

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

In the Matter of Letters Patent granted to CHRISTIAN EMIL BICHEL, of Berlin, in the Empire of Germany, for "Improvements in the manufacture of Explosive Compounds," dated 11th November, 1886, No. 14623.

NOTICE IS HEREBY GIVEN that the said C. E. BICHEL has applied for leave to amend the Specification numbered as above.

A copy of the Specification as proposed to be amended can be inspected at the Patent Office; and particulars of the proposed amendment were set forth in the Official Journal of the Patent Office issued on the 14th July, 1888.

Any person intending to oppose the said application must leave notice of objection thereto (on Form G) at the Patent Office, 25, Southampton Buildings, London, W.C., within one Calendar month from the date hereof.

Dated this 14th day of July, 1888.

H. READER LACK, Comptroller-General.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

In the Matter of Letters Patent granted to FRANCIS BRISTOW RAWES, of Stratford, in the County of Essex, for "Improvements in and in Apparatus for obtaining Sulphur and some of its Compounds, and in the treatment thereof, and also of the associated products," dated 22nd March, 1882, No. 1393.

NOTICE IS HEREBY GIVEN that the said F. B. RAWES has applied for leave to amend the Specification numbered as above.

A copy of the Specification as proposed to be amended can be inspected at the Patent Office; and particulars of the proposed amendment were set forth in the Official Journal of the Patent Office issued on the 18th August, 1888.

Any person intending to oppose the said application must leave notice of objection thereto (on Form G) at the Patent Office, 25, Southampton Buildings, London, W.C., within one Calendar month from the date hereof.

Dated this 18th day of August, 1888.

VOL. LVIII. No. 1501.

ON RHINANTHIN.

By Dr. T. L. PHIPSON, F.C.S.

In my *Journal of Medicine, &c.* (No. 100, p. 66), I noted that I had discovered a glucoside similar to digitalin in the leaves of the *Antirrhinum majus*, which flourishes abundantly in the sandy soils of Surrey. Further investigation of this substance has shown me that it is *rhinanthin*, a glucoside extracted twenty years ago by an Austrian chemist, H. Ludwig, from the seeds of *Rhinanthus hirsutus* and *R. crista-galli* (Rattle).

I find that rhinanthin exists rather plentifully in the leaves and stalks of the *Antirrhinum majus* (snapdragon), and that it shows a reaction by which it can be recognised, even when present in very minute quantity in an aqueous solution. According to my experiments, rhinanthin can be extracted from the plant either by means of methylic alcohol or by cold water. The former process gives the larger yield, but the latter gives a purer product, and is in every respect easier and more economical. The plant, when fresh, is very brittle, and can be easily broken up or cut into small fragments, leaves and stalks, and allowed to remain in water in a closed vessel for a few days. The liquid is then filtered, treated with a small quantity of sub-acetate of lead (which does not precipitate rhinanthin), filtered again, and the slight excess of lead having been separated from the filtrate, the latter is evaporated carefully (on a water-bath) almost to syrupy consistency, and then the vessel is allowed to remain in a warm dry place for a few days. In these circumstances rhinanthin forms transparent colourless rhombic crystals, which are very brilliant; it can be purified by a second crystallisation from water. It has a peculiar sweetish acid taste, and is very soluble in water and in alcohol.

The aqueous solution of rhinanthin, to which a few drops of hydrochloric acid are added, and then heated, gradually turns brown, finally deposits an amorphous dark brown precipitate (*rhinanthogen*), and the supernatant solution contains glucose.

This reaction is very sensitive, and precisely similar in appearance to the brown tint developed in solutions of glucose heated with soda (for instance, diabetic urine), only in the present case the colour is produced by acid. A perfectly clear colourless solution of rhinanthin in water, placed in a test-tube with a few drops of HCl and heated, turns gradually brown, and in a few moments, just after the solution has reached its boiling-point, it is quite dark and opaque. A copious precipitate of rhinanthogen results, in the form of a dark reddish brown amorphous powder, which can be filtered off and washed. The filtrate contains glucose.

This rhinanthogen dissolves in hot concentrated sulphuric acid, forming a greenish black solution. It is also attacked easily by nitric acid.

Ludwig has given to rhinanthin the formula $C_{58}H_{52}O_{40}$; my analyses of this substance do not exactly correspond with his single analysis, but lead to the formula—

Nevertheless, I have not had sufficient of the product at my disposal to pursue this subject further at present.

In treating the decoction by subacetate of lead it is well to employ as little as possible; the slight excess of lead can be removed either by carbonate of soda, phosphate of soda, or sulphuretted hydrogen. I prefer the latter, though it leaves a small quantity of acetic acid free in the liquid to be evaporated; for I have found by direct experiment that dilute acetic acid will not convert the

glucoside rhinanthin, as dilute HCl does, even after boiling for a considerable time; and on the water-bath the presence of a minute quantity of free acetic acid is not, in this case, prejudicial. It is best not to evaporate to a thick syrup, but to stop as soon as indications of crystallisation occur at the edge of the liquid. The capsule is then removed to a warm, dry place, where it remains for several days; the crystals thus formed are very white and brilliant.

The genera *Rhinanthus*, *Antirrhinum*, and *Digitalis* all belong to the same family of plants, and probably rhinanthin will be found to possess toxic properties; perhaps the toxic properties of *Linaria* (another closely allied genus) are due to it. But whatever may be its physiological properties, it is probable that rhinanthin, like digitalin, is very liable to allotropic changes and decomposition or oxidation. I believe that most of the substances extracted from *Digitalis* are really derived from allotropic or isomeric changes and from the decomposition of digitalin, and that these changes occur during the elaborate processes of extraction.

CHEAP APPARATUS FOR GENERATING SULPHURETTED HYDROGEN.

By J. MARTIN,

Lecturer at the Diocesan College, Rendeboosch, Cape Town.

THE apparatus shown below for generating H_2S for a practical class was designed by me a short time ago, and has given the greatest satisfaction on the score of both cheapness and convenience. The diagram will sufficiently explain its action.

A is a large glass cylinder, such as is used for deflagration experiments, tightly fitted with a well paraffined cork with three holes. C is a stout glass rod which passes through the centre hole in the cork and through a hole in the

bottom of a cylindrical porcelain vessel, E, which is supported by the end of the rod being flattened. The bottom of the porcelain vessel is drilled with several small holes. B is the delivery tube for the gas, and D is a short wide tube so placed that its lower end is perpendicularly over the interior vessel and closed at the top with a cork. The gas is of course generated by placing FeS in the porcelain vessel and acid in the lower part of the glass cylinder, and pushing down the rod. The strength of the current can be regulated with considerable nicety. To charge the apparatus for use I take out the cork from the tube O, and drop in small pieces of FeS, which fall into the porcelain vessel. The acid is sent in through the tube A by means of a funnel and india-rubber tubing. When the acid is the first to be used up, I draw up the interior vessel to the cork, take out the cork of the tube D, and invert the whole apparatus. The liquid of course runs out, but the FeS is retained so as to fall back again afterwards to bottom of the inside cylinder. I find that friction is sufficient to support the FeS, but to prevent accidents I place a small piece of caoutchouc tubing on the rod above.

The whole apparatus only costs about three shillings. It can of course be made of all sizes.

CHINESE TREATMENT OF COBALT ORES.

By THOS. IDE BOWLER.

HAVING lately had occasion to visit a Chinese glass factory in Canton, I was enabled to procure specimens of the *lâm po-li shek* (blue glass stone), used by these ingenious and very peculiar people for colouring glass blue, and used also for colouring porcelain. So far as I am aware, the Chinese have not the art of making colourless glass; they buy up old American or European broken glass, which they sort out according to colour and quality, and re-melt in pots 0.67 metre high $\times$ 0.40 metre in greatest breadth and 0.11 metre across the mouth, the thickness being about 0.04 metre. One, or occasionally two, of these pots are set in a small rectangular furnace of extremely primitive construction; the fuel used is anthracite, of which it takes about 3 to 4 cwts. to melt one pot of glass; the blow-irons are very light and short; the moulds are made of clay coated with coal-dust powder, while a heap of ashes and straw serves as lehr or annealing oven. Yet, astonishing as the statement may appear, these Chinese workmen, with their small quaint-looking and rough apparatus, were actually engaged in the successful separation of cobalt from iron, manganese, and nickel, the proportion of the cobalt being but 2.40 per cent. The ore in its rough state is first carefully washed, and each separate piece scrubbed with a brush to free it from adhering ferruginous clay; it is then dried and reduced to fine powder under a native tilt hammer-like arrangement, worked by the foot, the mortar and pestle being both of cast-iron; the resulting powder is then ground in a hand mill with water, a little powder being from time to time ladled into the mill and washed down with water. The powdered ore and water flows out into an earthenware receptacle, and at the end of the day a workman stirs the ore and water carefully together, leaving the same to settle until the next morning, when he carefully pours off the water and then proceeds to reject the upper portion of the powder, by which means he gets rid of almost all the gangue, the heavier portions below consisting, for the most part, of iron, manganese, nickel, and cobalt oxides. This bottom portion is then dried, mixed with a little borax, and stirred up in the pot with a lot of old broken glass. The colour for the first twelve hours is a dirty greenish black; this gradually gives way to a light blue, showing more or less the amethyst tint imparted by the manganese, but both the iron and nickel appear to have been almost completely deoxidised, for

after about thirty-six to forty hours, 'firing the' colours imparted by these two metals are scarcely apparent in the glass. The bottom portion of glass in the pot is discarded as black or worthless.

For painting on porcelain the Chinese frit this same ore with felspar, white kaolin clay, and a large quantity of borax; the frit thus produced is ground up to a very fine powder and used for painting upon the biscuit, the *modus operandi* being, in Canton, as follows:—The workman first takes the burned biscuit; he then coats it with a white glaze of borax, felspar, and clay, and when this is dry he paints upon it, burning in both glaze and colour at one operation. The biscuit kiln is a circular beehive-like arrangement, with a firing door for the wood fuel at one side and three low chimneys at the other, the openings into the chimneys being at the bottom of the kiln, opposite the firing door. This latter is almost completely closed by bricks during firing, leaving only a little hole, some few inches square, for insertion of the fir boughs and dried grass used as fuel.

The sample of ore examined showed:—

Iron oxides	35
Manganese oxides. . . .	13.10
Nickel oxides.	3.50
Cobalt oxide.	2.40
Gangue	46.00

The gangue consisted mainly of silica with aluminic silicates. The ore is found at the base of a range of sandstone hills near the town of Tsang-sheng, the geological formation being probably Upper Cambrian.

Geological research in China is carried on under extreme difficulty in a country where, outside the narrow limits of the treaty ports, one carries one's life in one's hand, and amongst a hostile population, whose most friendly greeting is "*Sat ne fanqui lo*" ("Behead you foreign devil") or "*pah shan*" ("mountain climber"), meaning tiger, and the expression is a sort of invitation to the neighbours to join in exterminating the obnoxious visitor.

By-the-bye, how is it that in almost any work treating on metals or alloys one finds reference to the expression "*pak-fong*"? There must be in scientific writings, I fear, a minimum of original research and a great deal of plagiarism. The first writer, probably one of the earlier Jesuits, in describing the well-known Chinese alloy of copper and nickel in varying proportions with zinc and some other metals, wrote "*pak-tung*," white copper, the correct Chinese term; a printer's error made it "*pack-fong*," and everybody else has copied from this. It should be "*pak-tung*."

Hong-Kong, July 16, 1888.

ON PALLADIUM ALLOYS IN WATCHES.

By Professor EDWIN J. HOUSTON.

At the meeting of the American Philosophical Society on April 6th last Professor Houston stated that he had concluded his experiments on the Paillard watches. The following results were reached, viz.:—

A watch whose balance-wheel, hair-spring, and escapement are made of the Paillard palladium alloys can not have its rate sensibly affected by the influence of any magnetic field into which it is possible to bring it while on the person of its wearer.

In order to test this, such watches were carried into exceedingly powerful magnetic fields, and although carefully rated, both before and after exposure, no sensible change in their rate could be detected.

Experiments showed that the palladium alloys are entirely destitute of any paramagnetic properties. As far as the amount of the alloys at the author's disposal permitted, experiments failed to show that they possessed any diamagnetic properties.

By CHARLES E. MUNROE.

† *American Journal of Science*, vol. i., [3], May, 1871.

	Grms.
Weight of ditto after dissolving the BaSO ₄ in hot concentrated H ₂ SO ₄	31·0640
Weight of ditto after second treatment with H ₂ SO ₄	31·0609
Weight of crucible complete.. .. .	30·6744
Weight of felt.. .. .	0·3863

Felts of this character may of course be obtained by similar means from easily decomposable salts of other metals than platinum, and such felts may be found to have useful applications.

It is probable that this method of producing a platinum sponge within a platinum tube may find useful applications in organic chemistry in addition to its use as a filter.—*Journal of Analytical Chemistry*, vol. ii., Part 3.

GEOMETRICAL ILLUSTRATIONS OF NEWLANDS' AND MENDELEEFF'S PERIODIC LAW OF THE ATOMIC WEIGHTS OF THE CHEMICAL ELEMENTS.*

By the Rev. SAMUEL HAUGHTON, M.D.

(Concluded from p. 95).

PART II.—THE THIRD AND FOURTH PERIODS OF SEVEN ELEMENTS FOLLOWING CHLORINE; OR, THE TITANIUM-GERMANIUM DOUBLE PERIOD.

I now proceed to the discussion of the third and fourth periods of seven elements each.

Third Period, or Titanium Period.

Element.	Atomic Weight.	Valency.
1. Potassium	39	Monad.
2. Calcium	40	Dyad.
3. Scandium*	44—45	Triad.
4. Titanium	48	Tetrad.
5. Vanadium	51	Triad.
6. Chromium	52	Dyad.
7. Manganese	55	Monad.

Fourth Period, or Germanium Period.

Element.	Atomic Weight.	Valency.
1. Copper	63	Monad.
2. Zinc	65	Dyad.
3. Gallium (<i>Ekaluminium</i>)	69	Triad.
4. Germanium (<i>Eka Silicon</i>)	72	Tetrad.
5. Arsenic	75	Triad.
6. Selenium	79	Dyad.
7. Bromine	80	Monad.

At the commencement of the year 1875 there were three unknown elements of this table, viz. :—

Gallium, found in 1875;
Scandium, found in 1879;
Germanium, found in 1886.

And it is the glory of the Periodic Law of Modern Chemistry that it predicted (approximately) the atomic weights of these three unknown elements and their valencies, which predictions were fulfilled by the successive discovery of the unknown elements.

In Plate IV., which is a representation of the third and fourth periods of Dr Reynolds's curve, we can see that a triad element is wanting between calcium and titanium, and both a triad and tetrad element wanting between zinc and arsenic. These missing elements were predicted and found.

It is quite true that there were three well-known

elements lying between manganese and copper, viz., iron, nickel, and cobalt; but these three elements did not conform to the rules of the Periodic Law, and their places have been taken in that law by scandium, gallium, and germanium.

They were like the "three children in the oven" described by Daniel (Shadrach, Meshach, and Abednego), who refused to worship the Golden Image or Periodic Law set up by Nebuchadnezzar and the modern chemists.

I hope to show in the present Paper that iron, nickel, and cobalt are not so refractory as they appear at first sight; but, on the contrary, ready to take their proper places on the chemical curve when rightly interpreted.

An inspection of Plate IV. shows (just as we found in the former curve in the case of the tetrad elements, carbon and silicon) that the line joining the tetrad elements, titanium and germanium, contains five elements, viz. :—

Ti | Va | Ca | Ga | Ge,

leaving nine elements free, which sit upon a general cubic—

K | Ca | Sc | Cr | Mn | Zn | As | Se | Br.

If we use the atomic weights and valencies of these nine elements (taking scandium = 44·3), we can find the equation of the cubic passing through these points, the form of which I have plotted in Plate V., and which has one real asymptote like the former cubic, but has a much more complex shape.* The dyad lines, both positive and negative, have a remarkable relation to the cubic curve. They are both very near the position of the horizontal tangent.

In fact, the positive dyad line intersects the cubic in three real points, viz. :—

79, 65·064, 65.

The first of these is the element selenium, and the third the element zinc, with another element almost identical with zinc in atomic weight, both points being nearly on the horizontal tangent.

The negative dyad line intersects the cubic in three real points also, viz. :—

40, 52, 56;

which represent exactly the atomic weights of the three elements—calcium, chromium, and iron.

Now, we must remember that the cubic curve was constructed without any reference to iron or its atomic weight, and it is very remarkable to find it taking its place on the curve after chromium, and near nickel and cobalt, which are not far off the dyad line.

In fact, the cubic curve points out by clinging to the dyad line from 52 to 59, the possibility of forming in that interval a number of elements similar to each other in physical and chemical properties. These elements have been actually formed, and are—

Chromium, Iron, Nickel, Cobalt.

Excepting these four elements formed on the cubic branch of the curve, the distribution of the remaining elements between the lineal and cubic branches is similar to that found in the curve described in Part I.

The first three elements are on the cubic, viz. :—

K | Ca | Sc.

The last three elements are also on the cubic branch, viz. :—

As | Se | Br.

The central elements alternate as before between the lineal and cubic branches, viz. :—

Mn cubic, Mn (*bis*) 57 lineal;
Cu lineal, Cu (*bis*) 64 cubic;
Zn cubic, Zn (*bis*) 66 lineal;

with a possibility of forming three other elements near them, which have not come into existence.

The remaining elements are formed in pairs on the

* Abstract of a Paper read before the Royal Irish Academy, May 14, 1888.

† The atomic weight of scandium lies between 44 and 45, but nearer to 44.

* I venture to call it a serpentine "whiplash" cubic.

made in a somewhat different manner, and were rather more extended than those of the above-mentioned chemists.

Most of my experiments were made in tubes closed at one end, and from 300 to 400 m.m. in length, and about 15 m.m. in diameter. A piece of platinum foil as long as the tube and of such a width as to pass freely into it, is placed in the tube, and kept in its place by a wire passing through the closed end, and projecting a few m.m. from it. The foil can be coated with platinum black by electrolysis, and the coating can be readily renewed without removing the foil by filling the tube with platinum chloride and connecting the wire passing through the sealed end with the zinc end of a battery; the other pole being a wire passing through a bit of small glass tube, and projecting a little from the closed end.

Platinum foil so prepared gradually loses its activity or power in bringing about combination. Between hydrogen and liquids this loss of activity for the most part merely results in a slower action, the nature of the change being the same. In the case of some gases, however, not only is the rate, but also the kind of the chemical change to some extent influenced by the activity of the platinum; but this may be due to the higher temperature produced, and not to any increased activity of the occluded hydrogen.

The efficiency of the prepared platinum can be readily tested by transferring electrolytic gases to the tube. Perhaps one or two experiments may not be out of place. A freshly-prepared tube was rapidly filled with a mixture of electrolytic gases; there was a rapid contraction for five or six seconds, followed by an explosion. In a similar tube which had been in use some months the contraction was much slower, taking from ten to fifteen minutes, and there was no explosion. In a tube containing foil which had not been coated or specially cleaned, the gases took about thirty hours to disappear.

The hydrogen was in most cases made by the electrolysis of pure dilute sulphuric acid, but in some cases by dilute sulphuric acid and zinc.

The experiments were generally made by filling the tube with the solution under trial, then displacing the solution with hydrogen and leaving the filled tube standing in the solution. With corrosive liquids, instead of the tubes just described, a V tube may be used, one limb of which is closed, and contains the prepared foil.

Nitric Acid.

A number of experiments have been made on the reducing action of occluded hydrogen on nitric acid and other oxygen compounds of nitrogen, and as the action of this gas can be studied on each compound apart from the rest, and as hydrogen in this condition resembles in its action nascent hydrogen, the results may reasonably be expected to throw a little light on the difficult and complicated subject of the action of metals on nitric acid.

A tube of electrolytic hydrogen was kept over nitric acid (sp. gr., 1.42) for six weeks; there was not, however, the least sign of any absorption. Similar tubes were kept for several months over acid somewhat more diluted than this, but no contraction of the volume of gas was noted in any case. This, then, shows the remarkable difference between ordinary or molecular hydrogen and the same element in a nascent state—a difference generally attributed to different atomic aggregation.

Hydrogen in contact with prepared platinum foil acts very readily on nitric acid. With acid of sp. gr. 1.42 red fumes make their appearance almost immediately and attain their maximum in a few minutes; there is then a gradual contraction in the gas, which is not quite absorbed for an hour or two unless the tube be agitated. The acid has by this means acquired a yellow appearance, being evidently reduced to nitrous acid.

With acid more diluted than this the results are similar, but the fumes are less red, and with an acid weaker still no red fumes appear; the action, therefore, is between the hydrogen and vapour of nitric acid.

If the acid (1.42) be diluted with four or five times its volume of water it is still acted on by hydrogen pretty rapidly, the contraction being from 40 to 50 m.m. per hour, depending on the freshness of the platinum black; the resulting acid has a nitrous smell and a reducing action on potassium permanganate. More diluted still the action is slower, but still there is an action, the lower limit of which I did not determine. With normal acid, however, the action is exceedingly slow; in seven days the contraction was only 30 m.m. in one of my experiments; with one-half normal (the weakest acid used in this mode of experimenting) the action was much the same.

Heat will greatly accelerate the action of hydrogen on dilute acid. For this purpose the tube is filled to the extent of about three-fourths with hydrogen, and either sealed up or closed with a good cork; it must be tied and then placed in a slanting position, so as to expose as much foil as possible to the liquid and gas in the water-bath.

Heated in this way with normal acid the absorption was almost complete in two hours, the acid in the tube giving the reaction for nitrous acid and also indicating a little ammonia with Nessler's reagent.

With half normal acid treated in the same way the result was pretty much the same; less nitrous acid and more ammonia appeared to be produced. With one-eighth normal acid the action was slower, but by six hours' heating in the water-bath nearly all the hydrogen had disappeared.

With $\frac{1}{10}$, $\frac{1}{20}$, and $\frac{1}{40}$ normal acid the action was very similar; in from five to eight hours the hydrogen almost or quite disappeared, and the residue in the tube gave in every instance the reactions of nitrous acid and ammonia. No acid more dilute than $\frac{1}{40}$ normal was experimented with.

The action of occluded hydrogen on these dilute solutions of nitric acid is interesting, as showing the activity of hydrogen in this condition; and for the purpose of comparison I have sometimes made an electrolysis of acid of the same strength, using a very weak current. Some of the hydrogen under these conditions will reduce a portion of the acid, but another part of the hydrogen always appears in a free state at the negative pole, showing that the gas in this condition can with difficulty, and only incompletely, reduce acid so dilute, which acid is freely acted on by occluded hydrogen if assisted by a moderate heat.

Nitrates.

The nitrates are all reduced by occluded hydrogen, but the action is not quite so rapid as with some other solutions. Hydrogen standing over a saturated solution of potassium nitrate was absorbed to the extent of 25 c.c. in six days; the solution in the tube smelt of ammonia, and showed that a nitrite had been formed. With sodium nitrate the action was very similar. Hydrogen sealed up in a tube containing platinum with a strong solution of potassium nitrate acted much more rapidly on exposing it to the heat of the water-bath. The gas had almost disappeared in two and a half hours, and the solution had a strong smell of ammonia and gave a reaction for a nitrite.

Hydrogen standing in a similar tube without platinum over a concentrated solution of nitre, gave no contraction in one month; and a similar sealed tube exposed to the heat of 100° C. in a water-bath for some hours showed no signs of contraction.

Crumpled platinum foil coated with platinum black was placed in a flask and half covered with a solution of KNO_3 ; when the flask was filled with hydrogen and heated on a water-bath the solution showed in a few minutes an alkaline reaction, and there was an evolution of ammonia. Other nitrates are also reduced. Those of barium and calcium, for instance, are reduced gradually at ordinary temperatures, and much more rapidly at the temperature of boiling water.

Cobalt Nitrate.—Hydrogen (without platinum) stood over a strong solution of cobalt nitrate for some weeks; but there were no signs of absorption. In the presence

of coated platinum, however, there was a gradual but slow contraction of the gas. In a week this amounted to a column 150 m.m. in height; on the foil there were a few spots of a greenish-blue colour, and a brownish-yellow flocculent matter deposited. Some of the same solution was sealed up in a tube with hydrogen and heated for one hour (in presence of platinum); at the end of that time all the hydrogen had disappeared.

Nickel Nitrate.—This compound behaves in a similar manner, being slowly acted on at ordinary temperatures, and by two hours' heating in the water-bath the action is complete. No action occurs without the platinum.

Lead Nitrate.—When treated in the same manner this body gave similar results; without the presence of platinum it gave no result, either hot or at ordinary temperatures.

Copper Nitrate.—Russell (*Journ. Chem. Soc.*, xxvii., 3, 1874) states that copper nitrate and some other substances appear to be reduced by hydrogen; no particulars of experiments are, however, recorded. I have kept hydrogen standing over a strong solution of this salt for some weeks without any obvious result; in the presence of platinum, however, the hydrogen is readily absorbed with a production of copper nitrite, apparently. (In one of my experiments a slight deposit of metallic copper seemed to be formed on the platinum foil, but this is not always the case). *Nitrates of mercury and bismuth* are acted on by occluded hydrogen.

Silver Nitrate.—Chemists are by no means unanimous as to the action of hydrogen on silver nitrate. A diluted solution of this salt is readily reduced by occluded hydrogen to a metallic state, small brilliant-looking crystals making their appearance on the foil. The action with platinum was about ten times as rapid as without, with a dilute solution; with a concentrated one the difference is not so marked. I did not see any reduction to nitrite mentioned by Russell in the paper above alluded to, but the reduction did not, I expect, go far enough to produce this salt.

From these experiments it appears that all nitrates are readily reduced by occluded hydrogen.

Chlorine, Bromine, and Iodine.

Chlorine in the dark does not, as is well known, combine with hydrogen. I kept a tube of hydrogen standing over chlorine water for seven days, but there was not the slightest contraction. In the presence of platinum, however, the contraction is at the rate of 50 or 60 m.m. per hour; but with chlorine and bromine the finely-divided platinum is liable to become detached from the foil, and hence the action, after a time, becomes slower.

Hypochlorous acid is reduced by hydrogen under the usual conditions of experiment.

Hydrogen standing over a saturated solution of KClO_3 showed no contraction in six weeks. In the presence of the prepared foil the action is fairly rapid, being at the rate of 10 m.m. per hour. The chlorate is reduced to chloride; a quantitative experiment accounted for all the hydrogen absorbed.

Potassium perchlorate is not acted on.

Bromine water acts pretty much the same as chlorine. Iodine in a solution of potassium iodide is acted on more slowly.

Bromates and iodates were not experimented with.

Concentrated Sulphuric Acid.

It is sometimes stated in text-books that hydrogen attacks concentrated sulphuric acid; *e.g.*, in Frankland's and Japp's "*Inorganic Chemistry*" the following note occurs:—"The use of concentrated sulphuric acid as a desiccating agent ought to be avoided if a very pure gas (hydrogen) is required, as hydrogen slowly reduces this acid in the cold, with formation of sulphurous anhydride." In order to test this, I kept pure hydrogen over pure concentrated sulphuric acid for three weeks. There was no sign of contraction, and the acid had no smell of SO_2 , and

not the least reducing action on potassium permanganate. The reducing action of hydrogen on this acid must therefore be extremely small to exhibit no action in three weeks, and I cannot help thinking that one might safely dry hydrogen by means of sulphuric acid, provided the gas be pure; should it contain sulphuretted or phosphoretted hydrogen it would be quite another matter.

In contact with prepared foil the action is very different. There is a steady but slow absorption, which amounted to 150 m.m. in three days. The acid, when examined, smelt strongly of SO_2 , and had a reducing action on potassium permanganate.

Hydrogen reduces H_2SO_3 , but the action is slow.

Permanganates.

Potassium permanganate is slowly reduced by hydrogen, but the action is very slow; in the presence of platinum it is much hastened; but even in this case it is slower than one would have expected, the upper surface of the foil soon becoming exhausted unless agitated.

Bichromates.

An acidulated solution of potassic bichromate was not reduced by hydrogen in six weeks without platinum; with platinum the action is steady and fairly rapid.

Ferric Salts.

Ferric salts are not reduced by prolonged contact with hydrogen. In presence of platinum ferric chloride is readily reduced, and the reduction proceeds with great regularity; if the platinum deposit be fresh the contraction will amount to 50 or 60 m.m. per hour. The greater regularity shown in the reduction of this salt, compared with some others, is owing no doubt to its solubility, thus preventing the upper layer from becoming exhausted.

Ferric sulphate is very readily reduced by hydrogen in presence of platinum. In my experiment the action seemed a little more rapid than with the chloride.

Warren (*CHEMICAL NEWS*, vol. lv., p. 49) has suggested the use of ferric salts instead of potassium bichromate as a fluid for the galvanic battery. I know nothing of its efficiency for that purpose, but in my experiments a concentrated solution was more readily reduced than the acidified bichromate.

Mercuric Salts.

Mercuric chloride was not reduced by hydrogen alone in six months. With platinum it rose 75 m.m. in twelve hours, and a crust of white powder (Hg_2Cl_2) coated the foil. After a time the action became much slower from exhaustion of the upper layer.

Platinum Salts.

Platinum chloride is slowly reduced by hydrogen alone in the cold. The presence of the prepared foil greatly accelerates the action, which is as great in one hour with the foil as in forty-eight hours without it. The upper layer is completely reduced, becoming quite colourless.

Ferricyanides.

Hydrogen standing over potassium ferricyanide was reduced by 15 m.m. in twelve months; with the foil it is pretty readily reduced to ferrocyanide.

Action of Hydrogen on Nitric Oxide in Presence of Platinum.

Although this paper deals chiefly with the reducing action of hydrogen, it may not be out of place to mention here a few experiments with nitric oxide and hydrogen. The subject is by no means a new one. Most chemical works record the fact that hydrogen and nitric oxide give rise to ammonia when led over gently-warmed spongy platinum, and the reducing action of nascent hydrogen on the same gas is employed in preparing hydroxylamine. The method I have adopted in studying the reducing

action of hydrogen seemed suited also to investigate the action of gases on each other, inasmuch as the residual gases can be readily measured and examined. I have made a great number of experiments with these gases, and some of the results seem worth recording.

The experiments were, for the most part, made in the same tubes I have already described, some experiments on a much larger scale. In some cases the experiments were made over mercury, generally over water. One volume of hydrogen and two volumes of nitric oxide standing over mercury gave a very regular action, and the results of the different experiments were constant and represented by the equation $2\text{NO} + \text{H}_2 = \text{N}_2\text{O} + \text{H}_2\text{O}$. (Although standing over mercury the gases were moist, as the tube was first filled with water, over which the mixed gases were collected. If the tube had been filled with mercury the finely-divided platinum would have amalgamated with the mercury and so lost its activity.) Equal volumes of nitric oxide and hydrogen, treated in the same way, gave a contraction equal to one-half the original volume, the residue being nitrogen.

Made over water, the results are pretty much the same; on the whole they are, perhaps, a little less regular, due, no doubt, to the solution of a little of the nitrous oxide in the water.

With a larger proportion of hydrogen the action is much more rapid, taking place in the course of a few minutes if the platinum is pretty active, and leaving a strongly alkaline residue. Similar experiments made on a larger scale gave very interesting results.

Hydrogen to the extent of 600 c.c. was collected in a cylinder, in the upper part of which a large piece of platinum foil was placed; 150 c.c. of nitric acid were added rapidly. There was an almost immediate action—first the water in the cylinder was somewhat depressed, and heavy whitish fumes appeared near the foil: there was then a pretty rapid contraction of the gas, till only 300 c.c. remained, 450 c.c. having disappeared. This action only took a few minutes, and considerable heat was developed during the change. The residue was chiefly hydrogen, but it contained a little nitrogen; all the nitric oxide had disappeared, and there was no nitrous oxide in the residue. The liquid was strongly alkaline, and gave the reaction for hydroxylamine.

Similar experiments have been made with like results, and the contraction is very often the same as the above, though sometimes it may be a little less.

Ammonia is formed at the same time, and the change might be represented as follows:—

This, however, does not account for the small amount of nitrogen resulting from the experiment. This is a very interesting reaction, but by no means an unexpected one, seeing that hydroxylamine is prepared by the action of nascent hydrogen on nitric oxide.

If the nitric oxide is added in a much smaller proportion than was used in the last-mentioned experiment (viz., 1 to 4 hydrogen) the action appears pretty much the same, but much slower; for instance, I added to 600 c.c. of hydrogen 50 c.c. of NO, and the action was not complete for one hour, when 150 c.c. had been absorbed; on adding another 50 c.c. a similar contraction takes place. After a time, however, the contraction is less than that just indicated.

These experiments show the influence of mass in determining chemical change. With a small amount of hydrogen the reduction is to nitrogen and nitrous oxide; when the hydrogen is greater in amount, ammonia and hydroxylamine are the chief products of the reaction.

As in these experiments the nature of the change depends largely on the mass of gases present, I tried the effect of the copper-zinc couple on nitric oxide by placing a piece of zinc in a tube, coating it with copper, and then filling the tube with nitric oxide. The action is not very rapid, and the gas left is from one-fourth to one-third of

the nitric oxide taken; ammonia and a little hydroxylamine are formed.

In this case, therefore, the hydrogen is to some extent capable of uniting with the nitrogen, but not nearly to the extent that it does when there is a large mass of hydrogen in presence of platinum.

In presence of platinum, nitric oxide is reduced by carbonic oxide, forming nitrous oxide or nitrogen, according to the quantity of CO present.

Nitric oxide is also reduced by ammonia in presence of platinum. Nitrous oxide is reduced by hydrogen, ammonia, and carbonic oxide in presence of platinum.

In a few experiments, when nitric oxide was mixed with the smaller proportions of hydrogen mentioned, there were slight indications of hyponitrous acid; in other cases, however, no trace of this body could be obtained. If this substance is formed, I believe its formation depends on the activity of the platinum.

These experiments may be considered as proving that hydrogen, in presence of finely divided platinum, possesses all the properties of nascent hydrogen. In many cases the action is slow, but in some it might perhaps be used as a means of reduction when the presence of sodium-amalgam or the copper-zinc couple is objectionable.—*Glasgow Philosophical Transactions.*

ON A METEORIC IRON FOUND IN 1884 IN THE SUB-DISTRICT OF YOUNDEGIN, WESTERN AUSTRALIA, AND CONTAINING CLIFTONITE, A CUBIC FORM OF GRAPHITIC CARBON.

By L. FLETCHER, M.A., F.C.S.,
President of the Mineralogical Society.

THIS iron was found on January 5, 1884, by Alfred Eaton, a mounted police constable, when on duty in the sub-district of Youndegin, at a spot distant about 60 chains (three-quarters of a mile) in a north-west direction from the top of Penkarrig Rock, and roughly estimated by him at 70 miles east of York, Western Australia; this must be about longitude $117^\circ 30'$ E. of Greenwich, latitude $31^\circ 30'$ S. Only one of four observed fragments having been brought in by Mr. Eaton, the late Captain Smith, Commissioner of the Police at Perth, sent him out to Penkarrig with a native assistant with instructions to bring in the other three, at the instance of the Rev. Charles G. Nicolay, Curator of the Geological Museum, Freemantle, to whom the late Mr. Edward T. Hardman, F.C.S., the Government Geologist, had expressed his belief in the meteoric origin of the iron. Eaton and his companion started off on horseback at 8 a.m. on February 28, encamped at a "rock hole" for the night, and leaving at 6 a.m. the next day, reached Penkarrig at 7.30 a.m. An unsuccessful search was made for fragments additional to those already observed. Leaving Penkarrig at 7 a.m. on March 1, they encamped at Morecanning for the night, and arrived at York Police-station at 7 o'clock on the following morning.

To the zeal and thoughtfulness of Mr. Nicolay we are indebted for the preservation of the specimens, and for the particulars of their discovery; by him, at the suggestion of Lady Barker, the largest and the smallest fragments have been generously presented to the British Museum through Mr. R. H. Scott, F.R.S., as Secretary of the Mineralogical Society.

The four fragments were lying loose on the surface, three of them close together, and the fourth about 15 ft. away; they weighed $25\frac{1}{2}$ lbs., 24 lbs., $17\frac{1}{2}$ lbs., and 6 lbs. respectively; in the opinion of Mr. Nicolay they seem to have formed a portion of a spherical mass, although they are individually irregular in shape. Scattered around the iron there were broken pieces, apparently belonging to a shell or outer covering, and of these a weight of 17

lbs. was collected. As the latter fragments consist essentially of magnetic oxide of iron, they are doubtless due to the action of the weather on the meteorite; the samples sent to the Museum have a laminated structure, and one of them is an inch in thickness.

The country around Youndegin is described as granitic, with dykes of quartz, and schistose rocks; there is a superficial covering of sandstone, in which, though widely distributed over the Colony, no fossils have yet been found; there is no appearance of iron ore at Youndegin, though, in many parts of the Colony, iron ores are found in abundance. The above circumstances indicate an extra-terrestrial origin for the iron.

The only meteoric iron previously discovered in Australia is that of Cranbourne, near Melbourne, 1500 miles distant from Youndegin.

The largest of the two fragments presented to the British Museum weighed 25½ lbs.; it is 12 inches long, 10 inches broad, and has a maximum thickness of 3 inches. In shape it is rudely convex at one side and concave at the other; its surface presents numerous spherical depressions. It is distinguished from all the meteoric irons in the British Museum collection by two cylindrical holes, completely traversing the iron from back to front; one of them has a diameter varying from 2 to 2½ inches, and a length of 1½ inches; the other is of nearly the same size; three similar annular openings characterise the iron of Tazewell, Claiborne County, Tennessee, U.S.A., described and figured by the late Professor Lawrence Smith.* The large Signet iron, preserved in the National Museum at Washington, is an almost complete ring†; the meteoric iron of Independence County, described lately by Mr. Hidden,‡ is likewise remarkable for the presence of a small hole.

The smallest fragment of the Youndegin iron, weighing 6 lbs., also in the British Museum, is likewise concavo-convex, but is without holes: it is 7 inches long, 4½ inches broad, and about 2 inches thick.

The fragment weighing 24 lbs. is similar to the last mentioned; it is 9½ inches long, 6 inches broad, and 4 inches thick: it is to be preserved in the Geological Museum, Freemantle.

The remaining fragment weighing 17½ lbs. has been presented to the Melbourne Museum, Victoria.

The specific gravity was determined from three small pieces of the larger fragment, freed from rust; the numbers obtained were 7.86, 7.85, and 7.72 respectively.

The large specimen was cut on the premises of the Museum by means of hack-saws, and was found to be so hard that three weeks were required for the severance of a fragment of which the cut face is not 2½ inches square; a larger section of another meteoric iron (Nejed) was made in one-third of this time. The surface was next worked down with hard files of increasing fineness, and lastly polished with felt and emery powder.

On this face are seen numerous sections of enclosures, mostly tabular, of a yellowish metallic mineral which is strongly attracted by a magnet; this was found to be Schreibersite (phosphide of iron and nickel); some of the enclosures are in parallelism, and parts, isolated on the surface of the iron, are lineally arranged; the edges of the plates are only approximately straight; starting from them, thin cracks containing Schreibersite traverse the surface of the section in irregular directions; one of the plates is an inch long and one-eighth of an inch thick.

No stony matter is visible on the polished surface.

Relative to copper sulphate the iron is almost immediately active.

After exposure to the action of bromine water or dilute nitric acid the section gives no definite figures, but assumes a damascene appearance, very like that of the Tucuman iron, and of some parts of that of Brazos; to the latter

iron it is very similar in the proportion and distribution of the Schreibersite: the British Museum sections of the Arva and Sarepta irons are also, in parts, somewhat similar to it in their general characters.

On warming a fragment weighing 7 grms., in dilute hydrochloric acid, the greater part dissolved, and there was left a small residue (56 milligrams) of yellowish metallic scales which are very strongly attracted by a magnet and contain phosphorus; they are doubtless Schreibersite, and identical with the enclosures visible on the polished surface.

None of the cubic crystals, described below, were present in this residue.

No sulphuretted hydrogen was detected in the gas evolved during the solution of the iron; this indicates the absence of troilite from the fragment under examination.

The sulphur precipitated on passing sulphuretted hydrogen into the solution was faintly brown; the colouration was found to be due to traces of copper, the constancy of which as an ingredient of meteoric iron has been insisted upon by Lawrence Smith.

Besides iron, only nickel, cobalt, and magnesium were found in the solution.

As the iron was too hard for its filings to be used as material for quantitative analysis, a large fragment, containing visible Schreibersite, was filed until free from rust; its weight was 83200 grms.; its specific gravity, at 14°·5 C., relative to water at 4° and allowing for displaced air, was 7.851 (uncorrected 7.86).

The fragment was dissolved in aqua regia in a porcelain dish, and evaporated to dryness, on the water bath; the residue was treated with strong hydrochloric acid, and again brought to dryness to expel the remaining traces of nitric acid; on warming with water containing some hydrochloric acid, it was found that there was a small insoluble residue, consisting wholly of minute bright opaque greyish black cubic crystals with metallic lustre. The solution itself was poured into a weighed double filter,* and the crystals were washed by decantation, the washings being passed through the double filter; the filter showed no change of weight. The weight of the crystals was found to be 3.1 milligrams.

The filtrate was made up to 1000 c.c., and portions, 125 c.c. each, were removed by means of pipettes.

In one portion sulphuric acid was sought for, but not a trace was found, indicating the absence of troilite from this fragment also.

Another portion was evaporated to dryness on the water-bath, and afterwards heated in an air-bath for three quarters of an hour, at a temperature of 140°—145° C.; no silica was obtained. The phosphoric acid in this portion was next concentrated in the manner recommended by Lawrence Smith,† precipitated as phospho-molybdate,‡ dissolved in ammonia, and weighed as magnesium pyrophosphate.

From a third portion the iron was separated by a double precipitation with sodium acetate, re-dissolved in hydrochloric acid, and re-precipitated with ammonia.§ After ignition it was reduced by heating in a current of hydrogen, and dissolved in dilute hydrochloric acid: in experiments on different portions variable minute quantities of silica were at this point obtained, and were derived probably from the reagents.

The nickel and cobalt were separated from the magnesium by ammonium sulphide, and weighed together both in the oxidised and metallic condition; after solution of the nickel and cobalt the latter was precipitated by potassium nitrite, and weighed as potassium cobalt sulphate.

CORRESPONDENCE.

DR. PETERS'S AMERICAN METHODS OF
COPPER SMELTING.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS (vol. lviii., p. 76) Mr. J. W. Westmoreland takes to task the able writer of the above valuable work—

1st. For saying that the Cornish system of fire assay "is so interwoven with the commercial customs of the Swansea Copper smelters, and its replacement by one of the more accurate wet methods would involve such a revolution in the price lists and methods of ore buying, that it is likely to maintain its sway in the great market of the world for an indefinite time."

2nd. For speaking approvingly of the electrolytic assay of copper.

3rd. For omitting to mention Brown's iodide process for determining copper.

With your kind permission I would like to make some remarks on Mr. Westmoreland's criticism.

1st. Dr. Peters's book has for its subject *American methods of smelting*, &c., and is intended primarily for American readers, and since the Cornish system of dry assay has obtained no foothold in the United States, a minute treatment of the subject was not called for, and Dr. Peters's mention of this assay is obviously entirely incidental and cursory. Nevertheless, it is difficult to see wherein the Doctor has erred. It is still true, as when Dr. Peters wrote his book, that the dry assay is, in England, interwoven with the customs of the copper trade; and the abolition of Swansea ticketings is simply a portion of the revolution referred to by him. But for the present the dry assay is still the basis on which copper-bearing materials are valued. How long this will continue it is—as Mr. Westmoreland admits—difficult to say, and Dr. Peters exercised a wise caution in saying the dry assay was "likely to maintain its sway for an indefinite time." It is only by an unwarranted extension of the meaning of the word "indefinite" that the slightest justification for criticism appears.

2nd. The electrolytic process has been largely used in the United States for the valuation of copper ores, &c., for a number of years. This, in itself, constitutes strong evidence in its favour, for American analysts and metallurgists possess, in full measure, the shrewdness and ability for which their nation is famous. But Mr. Westmoreland himself has borne very strong testimony to the value of the electrolytic process. In the early part of a paper in the *Journal of the Society of Chemical Industry* (vol. v., p. 49) he says:—"The processes I personally employ in the examination of all copper ores and products are E. O. Brown's iodide process, and the electro-deposition method." And, at that time, so great was his faith in this process that he took the results obtained by it as the standard by which he claimed to prove the accuracy of the iodide process. At page 55 of the same *Journal* he gives comparative assays ("taken from a large number") of 28 samples of ores, mattes, and precipitates, the produce of which varied from as low as 0.45 to as high as 86 per cent. The maximum difference between the iodide mean tests, which Mr. Westmoreland so highly commends, and the electrolytic mean tests which he now so strongly condemns, was 0.23, and this was in one instance only, with 28 per cent ore; whilst the next greatest difference—in one case only—was 0.19; and after these two the greatest difference was 0.12, the average difference for the remaining 26 assays (including this 0.12) being only 0.034.

3rd. But Mr. Westmoreland's gravest charge is, that Dr. Peters omits to mention the iodide test. Now, the iodide process has been known for many years, but until quite recently was believed to have only a limited appli-

cation, and was very little used in the assay of copper ores, &c. Mr. Westmoreland, in the paper above referred to (written in February, 1886), says:—"One or two analysts in this country use the iodide process. Since that date the number of analysts who have adopted the process has doubtless increased, but even yet the process cannot, by the greatest stretch of language, be said to be in common use; and as Dr. Peters's book is essentially a practical work on the metallurgy of copper, and not a text-book of analytical chemistry, his omission to mention what was, at the time he wrote, a discarded process, is quite justifiable. When the time comes for revising the work for another edition, and if the iodide process shall, in the meanwhile, have taken the position which Mr. Westmoreland (perhaps justly) believes its merits entitle it to, it will then be soon enough for Dr. Peters to take cognisance of this very interesting method of assaying."

On the general question of assaying and valuation of copper-bearing materials, on which Mr. Westmoreland has so ably written, I have no desire to enter further than to express the opinion that his latest dissertation might just as well have been written to another text.—I am, &c.,

W. M.

SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 7, August 13, 1888.

On Amorphous Antimony.—F. Hérard.—The author has obtained the allotropic modification of antimony, signalled by M. Gore, and resulting from the decomposition of antimony chloride, bromide, or iodide by the battery. He heated antimony to dull redness in a current of nitrogen, and observed a development of greyish vapours, which condensed in a grey powder on the sides of the glass tube in which the apparatus terminates. This powder consists of minute globules united together like the amorphous arsenic of Bettendorff; it contains 98.7 per cent of antimony. Its specific gravity at 0° is 6.22, that of crystalline antimony varying, according to Isidore Pierre, from 6.725 to 6.737. Amorphous antimony melts at 614°, whilst crystalline antimony melts at 440°. The author suggests that there is first formed an antimony nitride, which is decomposed in the cooler portions of the tube, depositing amorphous antimony.

Four New Zinc Titanates.—Lucien Levy.—The author has obtained these titanates by melting titanate acid with mixtures of zinc and potassium sulphates. The essential points are the temperature and the quantity of the flux. At dull redness the product is always the sesquibasic titanate. At bright redness it is one of the three others, and the nature of the product depends on the proportion between the weight of the flux and the weight of zinc sulphate.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 2.

Determination of Phosphoric Acid in Basic Slags. C. Brunnemann (*Chemiker Zeitung*).—The author digests 10 grms. slag with 30 to 50 c.c. of water in a beaker holding 400 to 500 c.c.; 80 to 100 c.c. of strong hydrochloric acid are added, 50 c.c. of nitric acid, and lastly 10 c.c. of strong sulphuric acid, and the liquid is boiled

for thirty to forty-five minutes. The hot liquid is then poured into a litre flask containing about 400 c.c. of hot water, and the beaker is rinsed out with hot water. The solution is diluted to about 900 c.c. to dissolve any calcium sulphate which has separated out, let cool, filled up to the mark and let settle; 50 c.c. of the clear liquid are then taken and evaporated on the water-bath until the excess of nitric and hydrochloric acid is expelled. The free sulphuric acid is cautiously neutralised with dilute ammonia until the residue in the capsule takes a brown colour. It is now evaporated to dryness, heated in the air-bath for half an hour to 110° to separate silica, 10 c.c. strong nitric acid are poured upon the residue, stirring well with a glass rod, 40 to 50 c.c. of boiling water are added; the liquid is filtered, the filter washed, and in the solution the phosphoric acid is determined by the molybdenum method. This method determines both the phosphorus present as phosphoric acid and that existing as phosphide, which Kennepohl considers to be very trifling. He therefore recommends the following process:—10 grms. slag are placed in a 500 c.c. flask, moistened with alcohol, 40 c.c. of hydrochloric acid of sp. gr. 1.12, and an equal volume of water, and the whole is heated in the water bath for at least half an hour. When cold the flask is filled up to the mark, the liquid is filtered, and 25 c.c. of the filtrate are taken without previous elimination of silica mixed with ammonia and molybdenum mixture, heated for fifteen minutes to about 80° , filtered when cold; the precipitate, washed with cold water containing a little nitric acid, dissolved in cold ammonia at $2\frac{1}{2}$ per cent, and precipitated with magnesia mixture.

Examination of the Artificial Colours Occurring in Trade.—E. Weingaertner.—A very valuable paper, but one incapable of abridgment, and too extensive for insertion in full. It treats of the colours insoluble in water, and of those which are sold in the state of pastes.

Determination of Lead in Tin Alloys.—G. Schwartz (*Chemiker Zeitung*).—One grm. of the alloy is rolled out as fine as possible, covered with 20 c.c. of strong hydrochloric acid and heated gently. As a rule, in half an hour the alloy is dissolved, leaving the antimony behind. To dissolve the latter bromine water is added until the liquid becomes yellow, the excess of bromine is expelled by boiling, the liquid diluted to 100 c.c., let cool, and poured, shaking it round, in a thin stream into a solution of 40 grms. commercial crystalline sodium sulphide in 150 c.c. water. After the lead sulphide has subsided the supernatant liquid is poured through a filter and the precipitate is washed with dilute ammonium sulphide (1 vol. ammonium sulphide prepared with 10 per cent ammonia and 9 vols. water). The filter and precipitate are put in a porcelain capsule, covered with a funnel, treated with a 10 c.c. nitric acid of sp. gr. 1.5, and as soon as the first violent reaction is over 5 c.c. of strong sulphuric acid. It is then warmed upon asbestos paste-board with a small flame, or until the contents of the capsule have become colourless or pale brownish, let cool, the funnel is spirted out with alcohol at 50 per cent, diluted therewith to 100 c.c., washed as usual, ignited, and weighed. The lead sulphate, after washing, is treated with basic ammonium tartrate, which dissolves everything except traces of lead oxide, which are collected and deducted.

The Examination of Extracts.—A. Kremel.—Instructions for ascertaining the purity of extracts of pomegranate bark, ratanhia, quassia, rhubarb, aconite, &c.

Detection of Sugar in Urine.—Marson.—The author adds to 8 c.c. of the sample 0.1 grm. ferrous sulphate, heats, adds 0.25 grm. potassa, and goes on heating for some minutes. If sugar is present the precipitate varies from dark green to black, and the supernatant liquid is more or less coloured. In a normal sample the precipitate is a greenish brown and the supernatant liquid is colourless.

Polarimetric Determination of Glycogen.—A. Cramer.—The author considers this method, as recom-

mended by Kütz, scarcely inferior to Brücke's gravimetric determination.

Pettenkofer's Reaction for Biliary Acids.—The colouration depends on the formation of furfural.

Titration of Phosphoric Acid in Urine with Uranium Solution.—J. Mercier.—The author considers that this process, as given by Malot, may be advantageously used if decoction of cochineal is employed as an indicator.

Detection of the Indican of Urine.—Michailow.—The disturbing influence of urobiline may be eliminated by acidulating, saturating with ammonium sulphate, extracting urobiline and its chromogenes by means of acetic ether, then adding hydrochloric acid and chloroform, and oxidising with weak bromine-water.

Relations of Colouring-matters pre-existing in Urine to the Humic Bodies.—L. von Udránszky.—The author does not indicate any analytical method based upon the reaction which he brings forward.

Atomic Weight of Oxygen.—E. H. Keiser.—The author obtains the value 15.872.

Atomic Weights of Silver and Copper.—W. N. Shaw.—From the *Philosophical Magazine*.

Atomic Weights of Cobalt and Nickel.—Clemens Zimmermann (completed by Alibegoff and Krüss).—The atomic weight of cobalt is 58.74 ($O=15.96$) or 58.89 ($O=58.89$). The atomic weight of nickel is 58.56 ($O=15.96$) or 58.705 if $O=16$.

Re-determination of the Atomic Weight of Tungsten.—J. Waddel.—From the *American Chemical Journal*, reproduced in the *CHEMICAL NEWS*.

NOTES AND QUERIES.

* * * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Estimating Aluminium with Sodium Thiosulphate.—Would any chemist kindly oblige me with his experiences as to the manipulation of Chancel's or Wöhler's method of estimating aluminium by means of sodium thiosulphate? We rarely obtain more than 40 per cent of the metal as oxide, the filtrate yielding the remainder on the addition of ammonia; nor have we been able to boil off the SO_2 in a few minutes, for the evolution of this gas continues as long as the solution is boiled. Chancel's equation in the *Comptes Rendus* is— $Al_2(SO_4)_3 + 3Na_2S_2O_3 = Al_2O_3 + 1\frac{1}{2}S_2 + 3SO_2 + 3Na_2SO_4$.—C. A. WARREN.

NOTICE.

The STUDENTS' NUMBER of the *CHEMICAL NEWS* will be published on Friday, September 21st. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the education, who have not yet forwarded the necessary information to our Office for publication in that Number, will confer a favour by sending it with the least possible delay.

Advertisements for this Number should reach the Office not later than Wednesday, the 19th prox.

ST. PAUL'S SCHOOL.—An Examination for filling up about Eighteen Vacancies on the Foundation will be held on the 12th September next.—For information apply to the Bursar, St. Paul's School, West Kensington.

ST. PAUL'S SCHOOL, West Kensington.

Candidates for Foundation Scholarships are particularly requested to notice that the date of the Examination has been postponed from September 5 to September 12 and following days.

WEGELIN AND HÜBNER, Halle-on-Saale

MACHINE WORKS AND IRON FOUNDRY.

Representatives: NICKELS & Co., 150, Holborn, London, E.C.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37,746,
with increased effect through abolishing the noxious spaces; best
Air-Pump for Compression and Evacuation; useful effect up to 90
per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment,
with Attachment for Filtration with Exclusion of Air; in Wood,
Iron, or Bronze every desired size

Experimental Filter Presses

in Wood, Iron or Bronze.
Filtration Experiments, if desired, carefully conducted in
our Laboratory).

Steam Pumps & Transmission Pumps,
horizontal, vertical, mounted on column, Wall Pumps, Pumps for
Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids.
"Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or
Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids,
any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof,
i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c.
Also Small Ice Machines for Families, Laboratories,
Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure
or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Com-
pound Steam Engines.
From 2—150 horse-power

Steam Water Pumps,

newest, most approved Construction, taking up little room, and
especially suitable for placing in Wells, with great efficiency; up
to largest sizes.

Compressors driven by Steam or Belt, for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon,
Ether, Alcohol, Acetone, Water; in Iron or Copper. (Extraction
Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.
Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans,
and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin
Refineries, Resin Distilleries, Paraffin Works, Tar Dis-
tilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest
References for our above-named Specialities on
Application.

CITY AND GUILDS OF LONDON INSTITUTE. TECHNICAL COLLEGE, FINSBURY.

S. P. THOMPSON, Principal.

DAY DEPARTMENT FOR STUDENTS NOT UNDER 14 YEARS
of age.

The College Courses of Instruction in Laboratory, Lecture-Room,
Workshop, and Drawing Office, for Mechanical Engineers, Electrical
Engineers, and Technical Chemists, COMMENCE on TUESDAY,
OCTOBER 2nd.

Chemical Laboratories, specially organised for Instruction in Tech-
nical Manufacturing Processes. Fee for Session, inclusive of Labora-
tories, Workshops, and Drawing Office, £9.

The Entrance Examination will take place on Wednesday, Sep-
tember 26th, at Ten o'clock a.m.

Scholarships of £30 a year each, and the Holl Scholarship of £20
a year, all renewable for two years, will be awarded (in accordance with
the several schemes) on the results of the Entrance Examination.

For particulars of Scholarships and programmes of Instruction
apply at the Technical College, Leonard Street, City Road, E.C., or
at Gresham College, E.C.

ASSAYER AND ANALYTICAL CHEMIST
SWANSEA

WILLIAM FOX, ANALYTICAL CHEMIST,
LABORATORY:
4, GREAT TOWER STREET, LONDON. E.C.
Analyses of Oils, Pigments, Varnishes, &c.

Silicates of Soda and Potash in the state of
Soluble Glass, or in CONCENTRATED SOLUTION of first
quality, suited for the Manufacture of Soap and other purposes
supplied on best terms by W. GOSSAGE and Sons, Soap
Works, Widnes, Lancashire.

London Agents, COSTE and Co., 19 and 20, Water Lane, Tower
Street, E.C., who hold stock ready for delivery.

The London Hospital and Medical College, MILE END, E.

The SESSION 1888-89 will commence on Monday, October 1st,
1888. The new buildings which were opened by T.R.H. the Prince
and Princess of Wales, on May 21st, 1887, afford more than double
the accommodation which was provided formerly.

Four Entrance Scholarships, value £60, £40, £30, and £20, will
be offered for competition at the end of September to new students. Fees
for lectures and hospital practice, 50 guineas in one payment, or 100
guineas in three instalments. All resident and other hospital ap-
pointments are free, and the holders of all the resident appointments
are provided with rooms and board entirely free of expense. The
resident appointments consist of five house physicians, five house
surgeons, one accoucheurship, and one receiving-room officer;
one senior dresser to out patients, dressers and maternity pupils also
reside in the Hospital. Special classes for the preliminary scientific
and intermediate M.B. Examinations of the University of London
and for the Primary and Pass Examinations for the Fellowship of
the Royal College of Surgeons of England are held throughout the
year. Special entries may be made for medical and surgical practice.
The London Hospital is now in direct communication by rail and
tram with all parts of the metropolis, and the Metropolitan, Metro-
politan District, East London, and South Eastern Railways have
stations within a minute's walk of the Hospital and College.

For prospectus and particulars apply, personally or by letter, to
MUNRO SCOTT, Warden.

VOL. LVIII. No. 1502.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

BATH MEETING, SEPTEMBER 5, 1888.

INAUGURAL ADDRESS OF THE PRESIDENT, SIR FREDERICK BRAMWELL, D.C.L., F.R.S., M.Inst.C.E.

THE late Lord Iddesleigh delighted an audience for a whole evening by an address on "Nothing." Would that I had his talents and could discourse to you as charmingly as he did to his audience, but I dare not try to talk about "Nothing." I do, however, propose, as one of the two sections of my Address, to discourse to you on the importance of the "Next-to-Nothing." The other section is far removed from this microscopic quantity, as it will embrace the "Eulogy of the Civil Engineer" and will point out the value to science of his works."

I do not intend to follow any system in dealing with these two sections. I shall not even do as Mr. Dick, in "David Copperfield," did—have two papers—to one of which it was suggested he should confine his Memorial and his observations as to King Charles's head. The result is, you will find, that the importance of the next-to-nothing and the laudation of the Civil Engineer will be mixed up in the most illogical and haphazard way throughout my Address. I will leave to such of you as are of orderly minds, the task of re-arranging the subjects as you see fit, but I trust—arrangement or no arrangement—that by the time I have brought my Address to a conclusion I shall have convinced you that there is no man who more thoroughly appreciates the high importance of the "next-to-nothing" than the Civil Engineer of the present day, the object of my eulogy this evening.

If I may be allowed to express the scheme of this Address in modern musical language I will say that the "next-to-nothing" "motive" will commonly usher in the "praise-song" of the Civil Engineer; and it seems to me will do this very fitly, for in many cases it is by the patient and discriminating attention paid to the effect of the "next-to-nothing" that the Civil Engineer of the present day has achieved some of the labours of which I now wish to speak to you.

An Association for the Advancement of Science is necessarily one of such broad scope in its objects, and is so thoroughly catholic as regards Science, that the only possible way in which it can carry out those objects at all is to segregate its members into various subsidiary bodies or sections engaged on particular branches of Science. Even when this division is resorted to it is a hardy thing to say that every conceivable scientific subject can be dealt with by the eight Sections of the British Association. Nevertheless, as we know, for fifty-seven years the Association has carried on its labours under Sections, and has earned the right to say that it has done good service to all branches of Science.

Composed, as the Association is, of a union of separate Sections, it is only right and according to the fitness of things that, as time goes on, your Presidents should be selected in some sort of rotation from the various Sections. This year it was felt by the Council and the Members that the time had once more arrived when Section G—the Mechanical Section—might put forward its claim to be represented in the Presidency; the last time on which

a purely engineering Member filled the chair having been at Bristol in 1875, when that position was occupied by Sir John Hawkshaw. It is true that at Southampton in 1882 our lamented friend Sir William Siemens was President, and it is also true that he was a most thorough engineer and representative of Section G; but all who knew his great scientific attainments will probably agree that, on that occasion, it was rather the Physical Section A which was represented, than the Mechanical Section G.

I am aware, it is said, Section G does not contribute much to pure Science by original research, but that it devotes itself more to the application of Science. There may be some foundation for this assertion, but I cannot refrain from the observation that when Engineers, such as Siemens, Rankine, Sir William Thomson, Fairbairn, or Armstrong, make a scientific discovery, Section A says it is made, not in the capacity of an Engineer, and therefore does not appertain to Section G, but in the capacity of a physicist, and therefore appertains to Section A—an illustration of the danger of a man's filling two positions, of which the composite Prince-Bishop is the well-known type. But I am not careful to labour this point or even to dispute that Section G does not do much for *original* research. I don't agree it is a fact, but, for the purposes of this evening, I will concede it to be so. But what then? This Association is for the "Advancement of Science"—the *Advancement* be it remembered; and I wish to point out to you, and I trust I shall succeed in establishing, that for the *Advancement* of Science it is absolutely necessary there should be the *Application* of Science, and that, therefore, the Section, which as much as any other (or, to state the fact more truly, which more than any other) in the Association *applies* Science, is doing a very large share of the work of *advancing* Science, and is fully entitled to be periodically represented in the Presidency of the whole Association.

I trust also I shall prove to you that applications of Science and discoveries in pure Science act and re-act the one upon the other. I hope in this to carry the bulk of my audience with me, although there are some, I know, whose feelings, from a false notion of respect for Science, would probably find vent in the "toast" which one has heard in another place—this "toast" being attributed to the Pure Scientist—"Here's to the latest scientific discovery: may it never do any good to anybody!"

To give an early illustration of this action and re-action, which I contend occurs: take the well-worn story of Galileo, Torricelli, and the pump-maker. It is recorded that Galileo first and his pupil Torricelli afterwards were led to investigate the question of atmospheric pressure by observing the failure of a pump to raise water by "suction" above a certain level. Perhaps you will say the pump-maker was not applying science, but was working without science. I answer, he was unknowingly applying it, and it was from that which arose in this unconscious application that the mind of the Pure Scientist was led to investigate the subject, and thereupon to discover the primary fact, of the pressure of the atmosphere, and the subsidiary facts which attend thereon. It may appear to many of you that the question of the exercise of pressure by the atmosphere should have been so very obvious, but little merit ought to have accrued to the discoverer; and that the statement, once made, must have been accepted almost as a mere truism. This was, however, by no means the case. Sir Kenelm Digby in his "Treatise on the Nature of Bodies" printed in 1658, disputes the proposition altogether, and says, in effect, he is quite sure the failure of the pump to raise water was due to imperfect workmanship of some kind or description, and had nothing to do with the pressure of the air; and that there is no reason why a pump should not suck up water to any height. He cites the boy's sucker, which, when applied to a smooth stone, will lift it, and he says the reason why the stone follows the sucker is this. Each body must have some other body in contact with it. Now, the stone being in contact with the sucker, there is no reason why

that contact should be broken up for the mere purpose of substituting the contact of another body, such as the air. It seems pretty clear, therefore, that even to an acute and well-trained mind, such as that of Sir Kenelm Digby, it was by no means a truism, and to be forthwith accepted when once stated, that the rise of water on the "suction side" of a pump was due to atmospheric pressure. I hardly need point out that the pump-maker should have been a member of "G." Galileo and Torricelli, led to reflect by what they saw, should have been members of "A" of the then "Association for the Advancement of Science."

But, passing away from the question of the value of the application of Science of a date some two and a half centuries ago, let us come a little nearer to our own time.

Electricity—known in its simplest form to the Greeks by the results arising from the friction on amber, and named therefrom; afterwards produced from glass cylinder machines or from plate machines; and produced a century ago by the "Influence" machine—remained, as did the discoveries of Volta and Galvani, the pursuit of but a few, and even the brilliant experiments of Davy did not suffice to give very great impetus to this branch of physical science.

Ronalds in 1823 constructed an electric telegraph. In 1837 the first commercial use was made of the telegraph, and from that time electrical science received an impulse such as it had never before experienced. Further scientific facts were discovered; fresh applications were made of these discoveries. These fresh applications led to renewed vigour in research, and there was the action and reaction of which I have spoken. In the year 1871 the Society of Telegraph Engineers was established. In the year 1861 our own Association had appointed a Committee to settle the question of electrical standards of resistance, which Committee, with enlarged functions, continued its labours for twenty years, and of this Committee I had the honour of being a member. The results of the labours of that Committee endure (somewhat modified, it is true), and may be pointed to as one of the evidences of the value of the work done by the British Association. Since Ronalds's time, how vast are the advances which have been made in electrical communication of intelligence, by land lines, by submarine cables all over the world, and by the telephone! Few will be prepared to deny the statement that pure electrical science has received an enormous impulse, and has been advanced by the commercial application of electricity to the foregoing and to purposes of lighting. Since this latter application scores, I may say hundreds, of acute minds have been devoted to electrical science, stimulated thereto by the possibilities and probabilities of this application.

In this country, no doubt, still more would have been done if the lighting of districts from a central source of electricity had not been since 1882 practically forbidden by the Act passed in that year. This Act had in its title the facetious statement that it was "to facilitate Electrical Lighting"—although it is an Act which, even modified as it has been this year, is still a great discouragement of free enterprise and a bar to progress. The other day a member of the House of Commons was saying to me: "I think it is very much to our discredit in England that we should have allowed ourselves to be outrun in the distribution of electric lighting to houses by the inhabitants of the United States, and by those of other countries." Looking upon him as being one of the authors of the "facetious" Act I thought it pertinent to quote the case of the French parricide, who, being asked what he has to say in mitigation of punishment, pleads "Pity a poor orphan"—the parricide and the legislator being both of them authors of conditions of things which they affect to deplore. I will say no more on this subject, for I feel that it would not be right to take advantage of my position here to-night to urge Political Economy views, which should be reserved for Section F. I will

merely, and as illustrative of my views of the value of the application of Science to Science itself, say there is no branch of physics pursued with more zeal and with more happy results than that of electricity with its allies, and there is no branch of Science towards which the public looks with greater hope of practical benefits; a hope that, I doubt not, will be strengthened after we have had the advantage of hearing one of the ablest followers of that science, Professor Ayrton, who, on Friday next, has been good enough to promise to discourse on "The Electrical Transmission of Power."

One of the subjects which, as much as (or probably more than) any other, occupies the attention of the engineer, and therefore of Section G, is that of (the so-called) Prime Movers, and I will say boldly that, since the introduction of printing by the use of movable type, nothing has done so much for civilisation as the development of these machines. Let us consider these prime movers—and, first, in the comparatively humble function of replacing that labour which might be performed by the muscular exertion of human beings, a function which at one time was looked upon by many kindly but short-sighted men as taking the bread out of the mouth of the labourer (as it was called), and as being therefore undesirable. I remember re-visiting my old schoolmaster, and his saying to me, shaking his head:—"So you have gone the way I always feared you would, and are making things of iron and brass to do the work of men's hands."

It must be agreed that all honest and useful labour is honourable, but when that labour can be carried out without the exercise of any intelligence, one cannot help feeling that the result is likely to be intellectually lowering. Thus, it is a sorry thing to see unintelligent labour, even although that labour be useful. It is but one remove from unintelligent labour which is not useful; that kind of labour generally appointed (by means of the tread-wheel or the crank) as a punishment for crime. Consider even the honourable labour (for it is useful, and it is honest) of the man who earns his livelihood by turning the handle of a crane, and compare this with the labour of a smith, who, while probably developing more energy by the use of his muscles than is developed by the man turning the crane-handle, exercises at the same time the powers of judgment, of eye, and of hand in a manner which I never see without my admiration being excited. I say that the introduction of prime movers as a mere substitute for unintelligent manual labour is in itself a great aid to civilisation and to the raising of humanity by rendering it very difficult, if not impossible, for a human being to obtain a livelihood by unintelligent work—the work of the horse in the mill, or of the turnspit.

But there are prime movers and prime movers—those of small dimensions, and employed for purposes where animal power or human power might be substituted, and those which attain ends that by no conceivable possibility could be attained at all by the exertion of muscular power.

Compare a galley, a vessel propelled with oars, with the modern Atlantic liner; and first let us assume that prime movers are non-existent, and that this vessel is to be propelled galley-fashion. Take her length as some 600 feet, and assume that place be found for as many as 400 oars on each side, each oar worked by three men, or 2400 men; and allow that six men under these conditions could develop work equal to one horse-power: we should have 400 horse-power. Double the number of men, and we should have 800 horse-power, with 4800 men at work, and at least the same number in reserve, if the journey is to be carried on continuously. Contrast the puny result thus obtained with the 19,500 horse-power given forth by a large prime mover of the present day, such a power requiring, on the above mode of calculation, 117,000 men at work and 117,000 in reserve; and these to be carried in a vessel less than 600 feet in length. Even if it were possible to carry this number of men in such a vessel, by no conceivable means could

their power be utilised so as to impart to it a speed of twenty knots an hour.

This illustrates how a prime mover may not only be a mere substitute for muscular work, but may afford the means of attaining an end, that could not by any possibility be attained by muscular exertion, no matter what money was expended or what galley-slave suffering was inflicted.

Take again the case of a railway locomotive. From 400 to 600 horse-power developed in an implement which, even including its tender, does not occupy an area of more than fifty square yards, and that draws us at sixty miles an hour. Here again, the prime mover succeeds in doing that which no expenditure of money or of life could enable us to obtain from muscular effort.

To what, and to whom, are these meritorious prime movers due? I answer: To the application of science, and to the labours of the civil engineer, using that term in its full and proper sense, as embracing all engineering other than military. I am, as you know, a Civil Engineer, and I desire to laud my profession and to magnify mine office; and I know of no better means of doing this than by quoting to you the definition of "civil engineering," given in the Charter of The Institution of Civil Engineers, namely, that it is "the art of directing the great sources of power in Nature for the use and convenience of man." These words are taken from a definition or description of engineering given by one of our earliest scientific writers on the subject, Thomas Tredgold, who commences that description by the words above quoted, and who, having given various illustrations of the civil engineer's pursuits, introduces this pregnant sentence:—

"This is, however, only a brief sketch of the objects of civil engineering, the real extent to which it may be applied is limited only by the progress of science; its scope and utility will be increased with every discovery in philosophy, and its resources with every invention in mechanical or chemical art, since its bounds are unlimited, and equally so must be the researches of its professors."

"The art of directing the great sources of power in Nature for the use and convenience of man." Among all secular pursuits, can there be imagined one more vast in its scope, more beneficent, and therefore more honourable, than this? There are those, I know—hundreds, thousands—who say that such pursuits are not to be named as on a par with those of literature; that there is nothing ennobling in them; nothing elevating; that they are of the earth, earthy; are mechanical, and are unintellectual, and that even the mere bookworm, who, content with storing his own mind, neither distributes those stores to others nor himself originates, is more worthily occupied than is the civil engineer.

I deny this altogether, and, while acknowledging, with gratitude, that, in literature, the masterpieces of master minds have afforded, and will afford instruction, delight, and solace for all generations, so long as civilisation endures, I say that the pursuits of civil engineering are worthy of occupying the highest intelligence, and that they are elevating and ennobling in their character.

Remember the kindly words of Sir Thomas Browne, who said, when condemning the uncharitable conduct of the mere bookworm, "I make not, therefore, my head a grave, but a treasure of knowledge, and study not for mine own sake only, but for those who study not for themselves." The engineer of the present day finds that he must not make his "head a grave," but that, if he wishes to succeed, he must have, and must exercise, scientific knowledge; and he realises daily the truth that those who are to come after him must be trained in science, so that they may readily appreciate the full value of each scientific discovery as it is made. Thus, the application of science by the engineer not only stimulates those who pursue science, but adds him to their number.

Holding, as I have said I do, the view that he who displaces unintelligent labour is doing good to mankind, I claim for the unknown engineer who, in Pontus, established the first water-wheel of which we have a

record, and for the equally unknown engineer who first made use of wind for a motor, the title of pioneers in the raising of the dignity of labour, by compelling the change from the non-intelligent to the intelligent.

With respect to these motors—wind and water—we have two proverbs which discredit them: "Fickle as the wind," "Unstable as water."

Something more trustworthy was needed—something that we were sure of having under our hands at all times. As a result, Science was applied, and the "fire" engine, as it was first called, the "steam" engine, as it was re-named, a form of "heat" engine, as we now know it to be, was invented.

Think of the early days of the steam engine—the pre-Watt days. The days of Papin, Savory, Newcomen, Smeaton! Great effects were produced, no doubt, as compared with no fire engine at all; effects so very marked as to extort from the French writer, Belidor, the tribute of admiration he paid to the "fire" engine erected at the Fresnes Colliery by English Engineers. A similar engine worked the pumps in York Place (now the Adelphi) for the supply of water to portions of London. We have in his work one of the very clearest accounts, illustrated by the best engravings (absolute working drawings) of the engine which had excited his admiration. These drawings show the open-topped cylinder, with condensation taking place below the piston, but with the valves worked automatically.

It need hardly be said that, noteworthy as such a machine was, as compared with animal power, or with wind or water motors, it was of necessity a most wasteful instrument as regards fuel. It is difficult to conceive in these days how, for years, it could have been endured that, at each stroke of the engine, the chamber that was to receive the steam at the next stroke was carefully cooled down beforehand by a water injection.

Watt, as we know, was the first to perceive, or, at all events, to cure, this fundamental error, which existed prior to his time in the "fire" engine. To him we owe condensation in a separate vessel, the doing away with the open-topped cylinder, and the making the engine double-acting; the parallel motion; the governor; and the engine indicator, by which we have depided for us the way in which the work is being performed within the cylinder. To Watt, also, we owe that great source of economic working—the knowledge of the expansive force of steam; and to his prescience we owe the steam jacket, without which expansion, beyond certain limits, is practically worthless. I have said "prescience"—foreknowledge—but I feel inclined to say that, in this case, prescience may be rendered "pre-Science" for I think that Watt *felt* the utility of the steam jacket, without being able to say on what ground that utility was based.

I have already spoken in laudatory terms of Tredgold, as being one of the earliest of our scientific engineering writers, but, as regards the question of steam jacketing, Watt's prescience was better than Tredgold's science, for the latter condemns the steam jacket, as being a means whereby the cooling surfaces are enlarged, and whereby, therefore, the condensation is increased.

I think it is not too much to say that engineers who, since Watt's days, have produced machines of such marvellous power—and, compared with the engines of Watt's days, of so great economy—have, so far as principles are concerned, gone upon those laid down by Watt. Details of the most necessary character—necessary to enable those principles to be carried out—have, indeed, been devised since the days of Watt. Although it is still a very sad confession to have to make, that the very best of our steam engines only utilises about one-sixth of the work which resides (if the term may be used) in the fuel that is consumed, it is, nevertheless, a satisfaction to know that great economical progress has been made, and that the 6 or 7 lbs. of fuel per horse-power per hour consumed by the very best engines of Watt's days, when working with the aid of condensation, is now brought down to about

one-fourth of this consumption; and this in portable engines, for agricultural purposes, working without condensation—engines of small size, developing only 20 horse-power; in such engines the consumption has been reduced to as little as 1·85 lbs. per brake horse-power per hour, equal to 1·65 lbs. per indicated horse-power per hour, as was shown by the trials at the Royal Agricultural Society's meeting at Newcastle last year—trials in which I had the pleasure of participating.

In these trials Mr. William Anderson, one of the Vice-Presidents of Section G, and I were associated, and, in making our report of the results, we adopted the balance-sheet system, which I suggested and used so long ago as 1873 (see vol. lii., pp. 154 and 155, of the *Minutes and Proceedings of the Institution of Civil Engineers*), and to which I alluded in my address as President of G at Montreal.

I have told you that the engineer of the present day appreciates the value of the "next-to-nothings." There is an old housekeeping proverb that, if you take care of the farthings and the pence, the shillings and the pounds will take care of themselves. Without the balance-sheet one knows that for the combustion of 1 lb. of coal, the turning into steam of a given quantity of water at a given pressure is obtained. It is seen, at once, that the result is much below that which should be had, but to account for the deficiency is the difficulty. The balance-sheet, dealing with the most minute sources of loss,—the farthings and the pence of economic working,—brings you face to face with these, and you find that improvement must be sought in paying attention to the "next-to-nothings."

Just one illustration. The balance-sheet will enable you at a glance to answer this among many important questions. Has the fuel been properly burnt?—with neither too much air nor too little.

At the Newcastle trials our knowledge as to whether we had the right amount of air for perfect combustion was got by an analysis of the waste gases, taken continuously throughout the whole number of hours' run of each engine, affording, therefore, a fair average: the analysis of any required portion of gases thus obtained was made in a quarter of an hour's time by the aid of the admirable apparatus invented by Mr. Stead, and, on the occasion to which I refer, manipulated by him. In one instance an excess of air had been supplied, causing a percentage of loss of 6·34. In the instance of another engine there was a deficiency of air, resulting in the production of carbonic oxide, involving a loss of 4 per cent. The various percentages of loss, of which each one seems somewhat unimportant, in the aggregate amounted to 28 per cent, and this with one of the best boilers. This is an admirable instance of the need of attention to apparently small things.

I have already said that we now know the steam engine is really a heat engine. At the York Meeting of our Association I ventured to predict that, unless some substantive improvement were made in the steam engine (of which improvement, as yet, we have no notion), I believed its days, for small powers, were numbered, and that those who attended the centenary of the British Association in 1931 would see the present steam engines in museums, treated as things to be respected, and of antiquarian interest to the engineers of those days, such as are the open-topped steam cylinders of Newcomen and of Smeaton to ourselves. I must say I see no reason, after the seven years which have elapsed since the York Meeting, to regret having made that prophecy, or to desire to withdraw it.

The working of heat engines, without the intervention of the vapour of water, by the combustion of the gases arising from coal, or from coal and from water, is now not merely an established fact, but a recognised and undoubted, commercially economical, means of obtaining motive power. Such engines, developing from 1 to 40 horse-power, and worked by the ordinary gas supplied by the gas mains, are

in most extensive use in printing works, hotels, clubs, theatres, and even in large private houses, for the working of dynamos to supply electric light. Such engines are also in use in factories, being sometimes driven by the gas obtained from "culm" and steam, and are giving forth a horse-power for, it is stated, as small a consumption as one pound of fuel per hour.

It is hardly necessary to remind you—but let me do it—that, although the saving of half a pound of fuel per horse-power appears to be insignificant when stated in that bald way, one realises that it is of the highest importance when that half-pound turns out to be 33 per cent of the whole previous consumption of one of those economical engines to which I have referred.

The gas engine is no new thing. As long ago as 1807 a M. de Rivaz proposed its use for driving a carriage on ordinary roads. For anything I know he may not have been the first proposer. It need hardly be said that in those days he had not illuminating gas to resort to, and he proposed to employ hydrogen. A few years later a writer in *Nicholson's Journal*, in an article on "flying machines," having given the correct statement that all that is needed to make a successful machine of this description is to find a sufficiently light motor, suggests that the direction in which this may be sought is the employment of illuminating gas, to operate by its explosion on the piston of an engine. The idea of the gas engine was revived, and formed the subject of a patent by Barnett in the year 1838. It is true this gentleman did not know very much about the subject, and that he suggested many things which, if carried out, would have resulted in the production of an engine which could not have worked; but he had an alternative proposition which would have worked.

Again, in the year 1861, the matter was revived by Lenoir, and in the year 1865 by Hugon, both French inventors. Their engines obtained some considerable amount of success and notoriety, and many of them were made and used; but in the majority of cases they were discarded as wasteful and uncertain. The Institution of Civil Engineers, for example, erected a Lenoir in the year 1868, to work the ventilating fan, but after a short time they were compelled to abandon it and to substitute an hydraulic engine.

At the present time, as I have said, gas engines are a great commercial success, and they have become so by the attention given to small things, in popular estimation—to important things, in fact, with which, however, I must not trouble you. Messrs. Crossley Brothers, who have done so much to make the gas engine the commercial success that it is, inform me that they are prosecuting improvements in the direction of attention to detail, from which they are obtaining greatly improved results.

But, looking at the wonderful petroleum industry, and at the multifarious products which are obtained from the crude material, is it too much to say that there is a future for motor engines worked by the vapour of some of the more highly volatile of these products,—true vapour,—not a gas, but a condensable body, capable of being worked over and over again? Numbers of such engines, some of as much as 4 horse-power, made by Mr. Yarrow, are now running, and are apparently giving good results,—certainly excellent results as regards the compactness and lightness of the machinery; for boat purposes they possess the great advantage of being rapidly under way. I have seen one go to work within two minutes of the striking of the match to light the burner.

Again, as we know, the vapour of this material has been used as a gas in gas engines, the motive power having been obtained by direct combustion.

Having regard to these considerations, was I wrong in predicting that the heat engine of the future will probably be one independent of the vapour of water? And, further, in these days of electrical advancement, is it too much to hope for the direct production of electricity from the combustion of fuel?

As the world has become familiar with prime movers, the desire for their employment has increased. Many a householder could find useful occupation for a prime mover of $\frac{1}{4}$ or $\frac{1}{2}$ horse-power, working one or two hours a day; but the economical establishment of a steam engine is not possible until houses of very large dimensions are reached, where space exists for the engine, and where, having regard to the amount of work to be done, the incidental expenses can be borne. Where this cannot be, either the prime mover, with the advantages of its use, must be given up as a thing to be wished for, but not to be procured, or recourse must be had to some other contrivance,—say to the laying on of power, in some form or another, from a central source.

I have already incidentally touched upon one mode of doing this, namely, the employment of illuminating gas as the working agent in the gas engine; but there are various other modes, possessing their respective merits and demerits,—all ingenious, all involving science in their application, and all more or less in practical use,—such as the laying-on of special high-pressure water, as is now being extensively practised in London, in Hull, and elsewhere. Water at 700 lbs. pressure per inch is a most convenient mode of laying on a large amount of power through comparatively small pipes. Like electricity, where, when a high electromotive force is used, a large amount of energy may be sent through a small conductor, so with water, under high pressure, the mains may be kept of reasonable diameters without rendering them too small to transmit the power required through them.

Power is also transmitted by means of compressed air, an agent which, on the score of its ability to ventilate, and of its cleanliness, has much to recommend it. On the other hand, it is an agent which, having regard to the probability of the deposition of moisture in the form of "snow," requires to be worked with judgment.

Again, there is an alternative mode for the conveyance of power by the exhaustion of air,—a mode which has been in practical use for over sixty years.

We have also the curious system pursued at Schaffhausen, where quick-running ropes are driven by turbines, these being worked by the current of the River Rhine; and at New York, and in other cities of the United States, steam is laid on under the streets, so as to enable domestic steam engines to be worked, without the necessity of a boiler, a stoker, or a chimney, the steam affording also means of heating the house when needed.

Lastly, there is the system of transmitting power by electricity, to which I have already adverted. I was glad to learn, only the other day, that there was every hope of this power being applied to the working of an important subterranean tramway.

These distributions from central sources need, as a rule, statutory powers to enable the pipes or wires to be placed under the roads; and, following the deplorable example of the Electrical Facilities Act, it is now the habit of the enlightened corporation and the enterprising town clerk of most boroughs to say to capitalists who are willing to embark their capital in the plant for the distribution of power from a central source—for their own profit, no doubt, but also, no doubt, for the good of the community—"We will oppose you in Parliament, unless you will consent that, at the end of twenty-one years, we may acquire compulsorily your property, and may do so, if it turns out to be remunerative, without other payment than that for the mere buildings and plant at that time existing." This is the way English enterprise is met, and then English engineers are taunted, by Englishmen—often by the very men who have had a share in making this "boa-constrictor" of a "Facilities Act"—that their energy is not to be compared with that which is to be found in the United States and other countries. Again, however, I must remember that I am not addressing Section F.

There is one application of science, by engineers, which is of extreme beauty and interest, and that cannot be

regarded with indifference by the agriculturists of this country. I allude to the Heat-withdrawing Engines (I should like to say "Cold-Producers," but I presume, if I did, I should be criticised) which are now so very extensively used for the importation of fresh meat, and for its storage when received here. It need hardly be said that that which will keep cool and sweet the carcasses of sheep will equally well preserve milk, and many other perishable articles of food. We have in these machines daily instances that, if you wish to make a ship's hold cold, you can do it by burning a certain quantity of coals—a paradox, if ever there was one.

In this climate of ours, where the summer has been said to consist of "three hot days and a thunderstorm," there is hardly need to make a provision for cooling our houses, although there is an undoubted need for making a provision to heat them. Nevertheless, those of us who have hot-water heating arrangements for use in the winter would be very glad indeed if, without much trouble or expense, they could turn these about, so as to utilise them for cooling their houses in summer. Mr. Loftus Perkins, so well known for his labours in the use of very high-pressure steam (600 to 1000 lbs. on the inch), and also so well known for those most useful high pressure warming arrangements which, without disfiguring our houses by the passage of large pipes, keep them in a state of warmth and comfort throughout the winter, has lately taken up the mode of, I will say it, producing "cold" by the evaporation of ammonia, and, by improvements in detail, has succeeded in making an apparatus which, without engine or pumps, produces "cold" for some hours in succession, and requires, to put it in action, the preliminary combustion of only a few pounds of coke or a few feet of gas.

As I have said, our climate gives us but little need to provide or employ apparatus to cool our houses, but one can well imagine that the Anglo-Indian will be glad to give up his punkah for some more certain and less draughty mode of cooling.

I now desire to point out how, as the work of the engineer grows, his needs increase. New material, or better material of the old kind, has to be found to enable him to carry out these works of greater magnitude. At the beginning of this century, stone, brick, and timber were practically the only materials employed for that which I may call standing engineering work,—i.e., buildings, bridges, aqueducts, and so on,—while timber, cast iron, and wrought iron were for many years the only available materials for the framing and principal parts of moving machines and engines, with the occasional use of lead for the pipes and of copper for pipes and for boilers.

As regards the cast iron, little was known of the science involved (or that ought to be involved) in its manufacture. It was judged of by results. It was judged of largely by the eye. It was "white," it was "mottled," it was "grey." It was known to be "fit for refining," fit for "strong castings," or fit for castings in which great fluidity in the molten metal was judged to be of more importance than strength in the finished casting. With respect to wrought iron, it was judged of by its results also. It was judged of by the place of its manufacture; but when the works of the district were unknown, the iron, on being tested, was classed as "good fibrous," although some of the very best was "steel-like," or "bad," "hot-short," or "cold-short." A particular district would produce one kind of iron, another district another kind of iron. The ore, the flux, and the fuel were all known to have influence, but to what extent was but little realised; and if there came in a new ore, or a new flux, it might well be that for months the turn-out of the works into which these novelties had been introduced would be prejudiced. Steel again—that luxury of the days of my youth—was judged by the eye. The wrought bars, made into "blister" steel by "cementation," were broken, examined, and grouped accordingly. Steel was known, no doubt, to be a compound of iron and carbon, but the im-

portance of exactness in the percentage was but little understood, nor was it at all understood how the presence of comparatively small quantities of foreign matter might necessitate the variation of the proportions of carbon. The consequence was that anomalous results every now and then arose to confound the person who had used the steel, and, falsifying the proverb "true as steel," steel became an object of distrust. Is it too much to say that Bessemer's great invention of steel made by the "converter," and that Siemens's invention of the open-hearth process, reacted on pure science, and set scientific men to investigate the laws which regulate the union of metals and of metalloids? and that the labours of these scientific men have improved the manufacture, so that steel is now thoroughly and entirely trusted? By its aid engineering works are accomplished which, without that aid, would have been simply impossible. The Forth Bridge, the big gun, the compound armour of the ironclad with its steel face, the projectile to pierce that steel face—all equally depend upon the "truth" of steel as much as does the barely visible hairspring of the chronometer, which enables the longitude of the ship in which it is carried to be ascertained. Now, what makes the difference between trustworthy and untrustworthy steel for each particular purpose? Something which, until our better sense comes to our aid, we are inclined to look upon as ridiculously insignificant—a "next-to-nothing." Setting extraneous ingredients aside, and considering only the union of iron and carbon, the question whether there shall be added or deducted one-tenth of 1 per cent (pardon my clumsy way of using the decimal system) of carbon is a matter of great importance in the resulting quality of the steel. This is a striking practical instance of how apparently insignificant things may be of the highest importance. The variation of this fraction of a percentage may render your boiler steel untrustworthy, may make the difference between safety in a gun and danger in a gun, and may render your armour-piercing projectile unable to pierce even the thinnest wrought-iron armour.

While thus brought incidentally to the subject of guns, let me derive from it another instance of the value of small things. I have in my hand a piece of steel ribbon. It is probable that only those who are near to me can see it. Its dimensions are one-fourth by one-sixteenth of an English inch, equal to an area of one sixty-fourth of a square inch. This mode of stating the dimensions I use for the information of the ladies. To make it intelligible to my scientific friends, I must tell them that it is approximately 0.00637 of a metre, by approximately 0.0019 of a metre, and that its sectional area is 0.000101283 (also approximately) of a square metre. This insignificant (and speaking in reference to the greater number of my audience) practically invisible piece of material—that I can bend with my hand, and even tie into knots—is, nevertheless, not to be despised. By it one reinforces the massive and important-looking A-tube of a 9.2 inch gun, so that from that tube can be projected with safety a projectile weighing 380 pounds at a velocity, when leaving the muzzle, of between one-third and one-half of a mile in a second, and competent to traverse nearly 12½ miles before it touches the ground. It may be said, "What is the use of being able to fire a projectile to a distance which commonly is invisible (from some obstacle or another) to the person directing the gun?" I will suggest to you a use. Imagine a gun of this kind placed by some enemy who, unfortunately, had invaded us, and had reached Richmond. He has the range table for his gun; he, of course, is provided with our Ordnance maps, and he lays and elevates the gun at Richmond, with the object of striking, say, the Royal Exchange. Suppose he does not succeed in his exact aim. The projectile goes 100 yards to one side or to the other; or it falls 250 yards short, or passes 250 yards over; and it would be "bad shooting" indeed, in these days, if nearly every projectile which was fired did not fall somewhere within an area such as this. In this suggested parallelogram of 100,000

square yards, or some 20 acres, there is some rather valuable property; and the transactions which are carried on are not unimportant. It seems to me that business would not be conducted with that calmness and coolness which are necessary for success if, say every five minutes, a 380-pound shell fell within this area, vomiting fire, and scattering its walls in hundreds of pieces, with terrific violence, in all directions. Do not suppose I am saying that similar effects cannot be obtained from a gun where wire is not employed. They can be. But my point is, that they can also be obtained by the aid of the insignificant thing which I am holding up at this moment—this piece of steel ribbon, which looks more suitable for the framework of an umbrella.

I have already spoken to you, when considering steel as a mere alloy of iron and carbon, as to the value of even a fraction of one per cent of the latter; but we know that in actual practice steel almost always contains other ingredients. One of the most prominent of these is manganese. It had for years been used, in quantities varying from a fraction of 1 per cent up to 2.5 per cent, with advantage as regards ductility, and as regards its ability to withstand forging. A further increase was found not to augment the advantage: a still further increase was found to diminish it; and here the manufacturer stopped, and, so far as I know, the pure scientist stopped, on the very reasonable ground that the point of increased benefit appeared to have been well ascertained, and that there could be no advantage in pursuing an investigation which appeared only to result in decadence. But this is another instance of how the application of science reacts in the interests of pure science itself. One of our steel manufacturers, Mr. Hadfield, determined to pursue this apparently barren subject, and in doing so discovered this fact—that, while with the addition of manganese in excess of the limit before stated, and up to as much as 7 per cent, deterioration continued, after this latter percentage was passed improvement again set in.

Again, the effects of the addition of even the very smallest percentages of aluminium upon the steel with which it may be alloyed are very striking and very peculiar, giving to the steel alloy thus produced a very much greater hardness, and enabling it to take a much brighter and more silver-like polish. Further, the one-twentieth part of 1 per cent of aluminium, when added to molten wrought iron, will reduce the fusing-point of the whole mass some 500 degrees, and will render it extremely fluid, and thus enable wrought-iron (or what are commercially known as "Mitis"—castings of the most intricate character) to be produced.

No one has worked more assiduously at the question of the effect of the presence of minute quantities, even traces, of alloys with metals than Professor Roberts-Austen, and he appears, by his experiments, to be discovering a general law, governing the effect produced by the mixture of particular metals, so that, in future, it is to be hoped, when an alloy is, for the first time, to be attempted, it will be possible to predict with reasonable certainty what the result will be, instead of that result remaining to be discovered by experiment.

I have just, incidentally, mentioned aluminium. May I say that we engineers look forward, with much interest, to all processes tending to bring this metal, or its alloys, within possible commercial use?

One more instance of the effect of impurities in metals. The engineer engaged in electrical matters is compelled, in the course of his daily work, frequently to realise the importance of the "next-to-nothing." One striking instance of this is afforded by the influence which an extremely minute percentage of impurity has on the electrical conductivity of copper wire: this conductivity being in some cases reduced by as much as 50 per cent, in consequence of the admixture of that which, under other circumstances, would be looked upon as insignificant.

Reverting to the question of big guns. According to

the present mode of manufacture, after we have rough-bored and turned the "A" tube (and perhaps I ought to have mentioned that by the "A" tube is meant the main piece of the gun, the innermost layer, if I may so call it, that portion which is the full length of the gun, and upon which the remainder of the gun is built up)—after, as I have said, we have rough-bored and turned this "A" tube, we heat it to a temperature lying between certain specified limits, but actually determined by the behaviour of samples previously taken, and then suddenly immerse it perpendicularly into a well some 60 feet deep, full of oil, the oil in this well being kept in a state of change by the running into it, at the bottom, of cold oil conveyed by a pipe proceeding from an elevated oil tank. In this way the steel is oil-hardened, with the result of increasing its ultimate tensile strength, and also with the result of raising its so-called elastic limit. In performing this operation it is almost certain that injurious internal strains will be set up: strains tending to produce self-rupture of the material. Experiments have been carried out in England by Captain Andrew Noble, and by General Maitland, of the Royal Gun Factory, by General Kalakoutsky, in Russia, and also in the United States, to gauge what is the value, as represented by dimensions, of these strains, and we find that they have to be recorded in the most minute fractions of an inch, and yet, if the steel be of too "high" a quality (as it is technically called), or if there has been any want of uniformity in the oil-hardening process, these strains, unless got rid of or ameliorated by annealing, may, as I have said, result in the self-rupture of the steel.

I have spoken of the getting rid of these strains by annealing, a process requiring to be conducted with great care, so as not to prejudice the effects of the oil-hardening. But take the case of a hardened steel projectile, hardened so that it will penetrate the steel face of compound armour. In that case annealing cannot be resorted to, for the extreme hardness of the projectile must not be in the least impaired. The internal strains in these projectiles are so very grave that for months after they are made there is no security that they will not spontaneously fracture. I have here the point of an 8-inch projectile, which projectile weighs 210 lbs.; this, with others, was received from the makers as long ago as March of this year, and remained an apparently perfect and sound projectile until about the middle of August—some five months after delivery—and, of course, a somewhat longer time since manufacture—and between August 6th and 8th this piece which I hold in my hand, measuring $3\frac{1}{4}$ inches by $3\frac{1}{4}$ inches, spontaneously flew off from the rest of the projectile, and has done so upon a surface of separation which, whether having regard to its beautiful regularity, or to the conclusions to be drawn from it as to the nature of the strains existing, is of the very highest scientific interest. Many other cases of self-rupture of similar projectiles have been recorded.

Another instance of the effect of the "next-to-nothing" in the hardening and tempering or annealing of steel. As we know, the iron and the carbon (leaving other matters out of consideration) are there. The carbon is (even in tool-steel) a very small proportion of the whole. The steel may be bent, and will retain the form given to it. You heat it and plunge it in cold water; you attempt to bend it and it breaks; but if, after the plunging in cold water, you temper it by carefully re-heating it, you may bring it to the condition fit either for the cutting-tool for metal, or for the cutting-tool for wood, or for the watch-spring; and these important variations of condition which are thus obtained depend upon the "next-to-nothing" in the temperature to which it is re-heated, and therefore in the nature of the resulting combination of the ingredients of which the steel is composed.

Some admirable experiments were carried out on this subject by the Institution of Mechanical Engineers, with the assistance of one of our Vice-Presidents, Sir Frederick Abel, and the subject has also been dealt with by an eminent Russian writer.

There is, to my mind, another and very striking popular instance (if I may use the phrase) of the importance of attention to detail—that is, to the "next-to-nothing." Consider the bicycles and tricycles of the present day—machines which afford the means of healthful exercise to thousands, and which will, probably within a very short time, prove of the very greatest possible use for military purposes. The perfection to which these machines have been brought is almost entirely due to strict attention to detail; in the selection of the material of which the machines are made; in the application of pure science (in its strictest sense) to the form and to the proportioning of the parts, and also in the arrangement of these various parts in relation the one to the other. The result is that the greatest possible strength is afforded with only the least possible weight, and that friction in working has been reduced to a minimum. All of us who remember the hobby-horse of former years, and who contrast that machine with the bicycle or tricycle of the present day, realise how thoroughly satisfactory is the result of this attention to detail—this appreciation of the "next-to-nothing."

Let me give you another illustration of the importance of small things, drawn from gunnery practice.

At first sight one would be tempted to say that the density of the air on the underside of a shot must, notwithstanding its motion of descent, be so nearly the same as that of the air upon the upper side as to cause the difference to be unworthy of consideration, but we know that the projectiles from rifled guns tend to travel sideways as they pass through the air, and that the direction of their motion, whether to the right or to the left, depends on the "hand" of the rifling. We know also, that the friction against liquid or against gaseous bodies varies with the densities of these bodies, and it is believed that, minute as is the difference in density to which I have referred, it is sufficient to determine the lateral movement of the projectile. This lateral tendency must be allowed for, in these days of long ranges, in the sighting and laying of guns, if we desire accuracy of aim, at those distances at which it is expected our naval engagements will have to be commenced, and perhaps concluded. We can no longer afford to treat the subject as Nelson is said to have treated it in one of his letters to the Secretary of the Admiralty, who had requested that an invention for laying guns more accurately should be tried. Nelson said he would be glad to try the invention, but that, as his mode of fighting consisted in placing his ship close alongside that of the enemy, he did not think the invention, even if it were successful, would be of much use to him.

While upon the question of guns, I am tempted to remark upon that which is by no means a small thing (for it is no less than the rotation of the earth), which in long-distance firing may demand attention, and that to an extent little suspected by the civilian.

Place the gun north and south, say in the latitude of London, and fire a 12-mile round such as I have mentioned, and it will be found that, assuming the shot were passing through a vacuum, a lateral allowance of more than 200 feet must be made to compensate for the different velocity of the circumference of the earth at 12 miles north or south of the place where the gun was fired, as compared with the velocity of the circumference of the earth at that place itself—the time of flight being in round numbers one minute.

At the risk of exciting a smile, I am about to assert that engineering has even its poetical side. I will ask you to consider with me whether there may not be true poetry in the feelings of the engineer who solves a problem such as this: Consider this rock, never visible above the surface of the tide, but making its presence known by the waves which rise around it: it has been the cause of destruction to many a noble vessel which had completed, in safety, its thousands of leagues of journey, and was within a few score miles of port; then dashed to pieces upon it? Here is this rock. On it build a lighthouse. Lay your foundations through the water, in the midst of

the turmoil of the sea; make your preparations; appear to be attaining success, and find the elements are against you and that the whole of your preliminary works are ruined or destroyed in one night; but again commence, and then go on and go on until at last you conquer; your works rise above ordinary tide-level; then upon these sure foundations, obtained it may be after years of toil, erect a fair shaft, graceful as a palm and sturdy as an oak; surmount it with a light, itself the produce of the highest application of science; direct that light by the built-up lens, again involving the highest application of science; apply mechanism, so arranged that the lighthouse shall from minute to minute reveal to the anxious mariner its exact name and its position on the coast. When you have done all this, will you not be entitled to say to yourself, "It is I who have for ever rendered innocuous this rock, which has been hitherto a dread source of peril"? Is there no feeling, do you think, of a poetical nature excited in the breast of the engineer who has successfully grappled with a problem such as this?

Another instance: the mouth of a broad river or, more properly speaking, the inlet of the sea has to be crossed at such a level as not to impede the passage of the largest ships. Except in one or two places the depth is profound, so that multiple foundations for supporting a bridge become commercially impossible, and the solution of the problem must be found by making high in the air a flight of span previously deemed unattainable. Is there no poetry here? Again, although the results do not strike the eye in the same manner, is there nothing of poetry in the work that has to be thought out and achieved, when a wide river or an ocean channel has to be crossed by a subterranean passage? Works of great magnitude of this character have been performed with success, and to the benefit of those for whose use they were intended. One of the greatest and most noble of such works, encouraged, in years gone by, by the Governments of our own country and of France, has lately fallen into disfavour with an unreasoning public, who have not taken the pains to ascertain the true state of the case.

Surely it will be agreed that the promotion of ready intercourse and communication between nations constitute the very best, and most satisfactory guarantees for the preservation of peace; when the peoples of two countries come to know each other intimately, and when they, therefore, enter into closer business relations, they are less liable to be led away by panic or by anger, and they hesitate to go to war the one with the other. It is in the interests of both that questions of difference which may arise between them should be amicably settled, and having an intimate knowledge of each other, they are less liable to misunderstand, and the mode of determination of their differences is more readily arranged. Remember, the means of ready intercourse and of communication, and the means of easy travel are all due to the application of science by the engineer. Is not therefore his profession a beneficent one?

Further, do you not think poetical feeling will be excited in the breast of that engineer who will in the near future solve the problem (and it certainly will be solved when a sufficiently light motor is obtained) of travelling in the air—whether this solution be effected by enabling the self-suspended balloon to be propelled and directed, or, perhaps better still, by enabling not only the propulsion to be effected and the direction to be controlled, but by enabling the suspension in the air itself to be attained by mechanical means?

Take other functions of the Civil Engineer—functions which, after all, are of the most important character, for they contribute directly to the prevention of disease, and thereby not only prolong life, but do that which is probably more important—afford to the population a healthier life while lived.

In one town, about which I have full means of knowing, the report has just been made that in the year following the completion of a comprehensive system of sewerage,

the deaths from zymotic diseases had fallen from a total of 740 per annum to a total of 372—practically one-half. Has the engineer no inward satisfaction who knows such results as these have accrued from his work?

Again consider the magnitude and completeness of the water supply of a large town, especially a town that has to depend upon the storing-up of rain water: the provision which takes into account, not merely the variation of the different seasons of the year, but the variation of one year from another; that, having collated all the stored-up information, determines what must be the magnitude of the reservoirs to allow for at least three consecutive dry years, such as may happen; and that finds the sites where these huge reservoirs may be safely built.

All these—and many other illustrations which I could put before you if time allowed—appear to me to afford conclusive evidence that whether it be in the erection of the lighthouse on the lonely rock at sea; whether it be in the crossing of rivers, or seas, or arms of seas by bridges or by tunnels; whether it be the cleansing of our towns from that which is foul; whether it be the supply of pure water to every dwelling, or the distribution of light, or of motive power; or whether it be in the production of the mighty ocean steamer, or in the spanning of valleys, the piercing of mountains, and affording the firm secure road for the express train; or whether it be the encircling of the world with telegraphs, the work of the Civil Engineer is not of the earth earthy, is not mechanical to the exclusion of science, is not unintellectual; but is of a most beneficent nature, is consistent with true poetical feeling, and is worthy of the highest order of intellect.

THE AUSTRALASIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE formation of this Association, which already gives promise of being a great success, was first suggested by Professor Liversidge, of the Sydney University, during the Exhibition in Sydney, in 1879, but matters at that time not being considered quite ripe for it, the formation of the Association was again brought forward through the press in the year 1884. It was then suggested that, as it did not seem likely that the British Association would see their way to visit Australia during the Centennial year, an Australasian Association should be formed, on the same lines as the British Association, in order to bring about a federation or union of the members of the various scientific societies throughout Australasia.

It was also suggested that the first general meeting should be held in Sydney on the one-hundredth anniversary of the foundation of the Colony, as it was at that time thought there would be an International Exhibition in Sydney to celebrate that event. In furtherance of this object a preliminary meeting of delegates was held in Sydney in November, 1886, the project having met with the approbation and support of almost all the learned and scientific societies of Australasia.

At this meeting the formation of the Australasian Association for the Advancement of Science was agreed to unanimously, the rules of the British Association being adopted until the first general meeting, which it was decided should be held in Sydney during the year 1888.

In accordance with another resolution passed at the meeting of delegates the election of officers for the year took place in March of the present year, Mr. H. C. Russell, B.A., F.R.S., Government Astronomer, being elected President, Sir Edward Strickland, K.C.B., F.R.G.S., Hon. Treasurer, and Professor Liversidge, M.A., F.R.S., and Dr. George Bennett, F.L.S., Hon. Secs.

The formation of the Council was afterwards proceeded with, each learned or scientific society electing one representative for every hundred of its members; and the Chief

Justice, Minister for Public Instruction, the Chancellor and Vice-Chancellor of the Sydney University, the Mayor of Sydney, and the Presidents of the Royal Societies in other Colonies were elected Vice-Presidents for the year.

The Presidents of Sections were then elected, the gentlemen chosen being all resident in other Colonies than New South Wales, whilst the Secretaries of Sections, as a matter of necessity, were elected from amongst residents in Sydney.

The Association is hence thoroughly Australasian in its character, and the succeeding general meetings are to take place in turn in the capitals of the other Colonies, the executive officers being elected year by year by the Colony in which the meeting is held.

The first general meeting was to be held at the Sydney University, the opening ceremony, at which His Excellency the Governor will be present, taking place on Tuesday evening, August 28th, when the Presidential Address was delivered.

On the following day the Sectional meetings for the reading and discussion of papers commenced, and it is thought that the principal portion of the business will close with the end of the week.

Up to the present time the titles of about ninety papers have been sent in by gentlemen of distinction in Science, Literature, and Art in the different Colonies, and it seems probable that this number will be considerably increased before the meeting.

It may therefore be anticipated that the nature of the work done by the Association during the first year of its existence will be of a highly important and useful character.

The more solid work of the meeting is to be lightened by excursions to various places of interest to geologists, botanists, and others; and efforts are being made to provide for the entertainment and comfort of visiting members as far as possible, so that they may spend their time to the best advantage.

The various steamship companies have arranged to carry members proceeding to Sydney to attend the meeting at a reduction of 20 per cent on the ordinary rates, and it is anticipated that liberal concessions will also be granted in the railway fares.

The rules, as already mentioned, are practically the same as those of the British Association, and all who join the Association before the first general meeting in August become original members, without entrance fee, the subscription of £1 entitling members to receive the publications of the Association gratis.

The number of members at the end of July exceeded 400.

ON A METEORIC IRON FOUND IN 1884 IN THE SUB-DISTRICT OF YOUNDEGIN, WESTERN AUSTRALIA, AND CONTAINING CLIFTONITE, A CUBIC FORM OF GRAPHITIC CARBON.

By L. FLETCHER, M.A., F.C.S.,
President of the Mineralogical Society.

(Concluded from p. 107).

In the way detailed the composition of the iron was found to be as follows:—

Iron	92.67
Nickel	6.46
Cobalt	0.55
Copper	trace
Magnesium	0.42
Phosphorus	0.24
Sulphur	none
Insoluble cubes	0.04

Total 100.38

If the phosphorus be assumed to be wholly present in combination with iron and nickel, as Schreibersite, with the formula Fe_2NiP , and percentage composition—Iron 55.53, nickel 29.09, phosphorus 15.38, the above will correspond to—

Nickel-iron	98.82
Schreibersite	1.56

100.38

As no opaque greyish-black mineral with a metallic lustre, and insoluble in aqua regia, is recognised as occurring in cubic crystals, the satisfactory determination of the nature of the insoluble residue of 3.1 milligrms. was expected to be a matter of some difficulty; further, two fragments of the iron, weighing 7 grms. and 2 grms. respectively, had not yielded a single crystal, and there was thus a possibility of the crystals being so localised as to render impracticable an increase of the quantity of material available for experiment.

The crystals were about a hundred in number, the average thickness of the larger ones being one-fourth of a millimetre (one-hundredth of an inch).

On all the crystals the faces of the cube are predominant; many are sharply defined simple cubes; some have their edges truncated by faces of the dodecahedron, as was proved by measurement on the goniometer; in others the edges are replaced by rounded faces of a tetrakis-hexahedron; or again, one or more of the cube-faces is replaced by a very obtuse, almost flat, square pyramid. One of the cubes shows re-entrant edges suggesting a lamellar growth. A little group of three parallel crystals was observed.

One of the crystals having been dropped on to a thin layer of red sealing-wax melted on a glass plate, was held sufficiently firm by the cooled wax to allow of its hardness and streak being determined. The hardness is greater than that of rock-salt, and less than that of calcite; it may be expressed as 2.5. The streak on white unglazed porcelain is black and shining.

The crystals are not affected by a magnet.

Of four crystals, two sank to the bottom, and two floated near the surface of a solution of sp. gr. 2.12.

The crystals remain unaltered when heated in a glass tube, closed at one end.

They are unattacked by nitro-hydrochloric, sulphuric, or hydrofluoric acids.

They float unaltered in beads of borax, microcosmic salt, or sodium carbonate, held in a blowpipe flame.

On dissolving in water a bead of sodium carbonate and potassium nitrate, in which three of the crystals had been heated, only one crystal was seen, and this was much reduced in size; the solution of the bead gave no evidence of the presence of chromium.

Similar beads, in each of which a crystal had been dissolved, were tested for phosphoric and silicic acids with negative results; nor did the solution of a bead in hydrochloric acid give any precipitate with ammonia, ammonium sulphide, ammonium carbonate, or sodium phosphate.

Heated in a combustion tube in a current of oxygen, hydrogen, or chlorine, they are unattacked, even when the glass begins to melt.

Heated in a long narrow porcelain crucible in air or oxygen with the table-blowpipe they appear unaltered, but in a shallow uncovered platinum capsule or small porcelain crucible they slowly disappear, without flame; from the platinum capsule the disappearance was complete, but in the porcelain crucible there was sometimes left an almost imperceptible black residue; projecting from this, in one instance, minute fibres were seen with the microscope.

Heated with potassium nitrate in a crucible over a Bunsen burner they are unattacked, but disappear very slowly, without deflagration, when heated with a table-blowpipe.

In density, colour, and streak, and in its chemical behaviour, the residual mineral thus resembles native graphite, but it is considerably harder, and presents itself

in well defined crystals which belong, like the other crystallised form of carbon, the diamond, to the cubic system; terrestrial graphite, when crystallised, is found only as tabular crystals so indistinctly formed that doubt has long existed as to whether they should be referred to the hexagonal or monosymmetric system.

From other fragments of the iron, weighing altogether about 10 grms., thirty more of the cubic crystals were obtained.

Graphitic carbon, sometimes in large nodules, has been found concentered in several meteoric irons, and has been subjected to careful examination by Lawrence Smith;* in structure and powder it is not unlike the compact Borrowdale graphite, and differs completely both from the scaly graphite found native and from that which is presented by certain cast irons; on the other hand, its conversion into graphitic acid by oxidising reagents is more rapid than that of any terrestrial native graphite experimented upon by him.

In a paper entitled "Graphite pseudomorphous after Iron Pyrites," Haidinger,† in 1846, described some graphitic crystals which are doubtless identical in their general characters with those furnished by the Younegin iron; his observation, however has been forgotten, and is without record in modern meteoric literature. The crystals, of the size, number, and completeness of which Haidinger makes no mention, were obtained by him from a nodule of graphite which had dropped out of the Arva meteoric iron; impressed by the similarity in shape of the nodules of graphite and sulphide of iron present in this meteorite, and by the circumstance that the two minerals are occasionally lying side by side, Partsch conceived the idea that one was pseudomorphous after the other; and Haidinger and Partsch became convinced of the correctness of this idea by the form of the graphitic crystals, on the cube-edges of which they believed there were faces of the pentagonal dodecahedron $\pi \{120\}$, so common a feature of the crystals of iron pyrites. Of the incorrectness of this explanation of the graphitic crystals there can be no doubt; the presence of iron pyrites, crystallised or massive, has even yet not been established for any meteorite; the meteoric sulphide of iron being not the bisulphide but the protosulphide, and having since received from Haidinger himself the specific name of troilite (1863).

Nor is Haidinger's interpretation of the form of the Arva graphitic crystals beyond criticism, for Gustav Rose,‡ to whom the crystals had been kindly sent for inspection, expressed an opinion that the mode of replacement of the cube-edges was suggestive rather of holo-symmetry than of hemi-symmetry—an interpretation which would exclude iron pyrites as a possible antecedent mineral.

The Younegin graphitic crystals support the view entertained by Rose; the existence of the dodecahedron-face, of which there is goniometrical proof, is of itself quite sufficient to show that the crystalline form is distinct from that of iron pyrites. The iron pyrites theory being abandoned, and the fact being recognised that no mineral constituent of meteorites has yet been found which crystallises in forms similar to those of the graphitic crystals, there naturally arises a feeling of doubt as to the correctness of the view according to which they are of the pseudomorphic origin, and a question as to whether they do not represent a third allotropic condition of crystallised carbon; it is conceivable, in fact, that the explanation by pseudomorphism really resulted from the supposed similarity of the form of the crystals to that of iron pyrites.

Bischoff§ denies the possibility of explaining the pseudomorphism of terrestrial minerals by any other process than the slow action of water, of which there is no evidence in meteorites; and though it would be unsafe to argue that only in this way could meteoric pseudomorphs be

produced, there is sufficient difficulty in accounting for the occurrence of pseudomorphs in the interior of a mass of iron to compel us to demand strong evidence before the pseudomorphism of the graphitic crystals is granted, more especially when we have regard to the fact that no other graphitic pseudomorph has yet been established either in meteoric or in terrestrial minerals.

The Younegin crystals were accordingly examined under the microscope with a quarter-inch objective. One of the dodecahedron-faces, an elongated hexagon in shape, showed ridges symmetrical to the truncated edge of the cube, and parallel to the two short edges of the hexagon which met in one of the trigonal quins. From the faces of several of the crystals spring acutely conical, almost acicular, projections of the same material, more or less irregular in shape; sometimes there is an approximately spherical growth covering a greater part of a cube-face, and occasionally one of the spherical growths is broken, and is seen to be merely a thin, now empty, shell, of which the bottom is the face of the cube; in shape this is suggestive of a burst bubble. One specimen was apparently a fragment of a hollow cube.

The crystals are easily frangible; one of them, when gently pressed between a glass plate and a sheet of paper, was flattened out and was split parallel to the edges of one of the cube-faces, as if the crystal had been hollow and had collapsed. Examined under the microscope, one of the thin fragments was found to consist of several distinct layers parallel to a cube-face, and on its interior surface was seen a bright triangular face in the zone of a cube-edge; another thin square fragment, doubtless a face of the original cube, has a granulated internal surface, and its edges are bent at right angles to its plane, as if it had formed a portion of a shell. The powder of this crystal was scaly, and gave a scarcely visible streak on the paper. Three other crystals were found to be solid. No cleavage surfaces were visible on the fragments.

The crystals appear to be quite homogeneous in their material.

Although some of these characters point, more or less distinctly, to a pseudomorphic origin of the crystalline form, it cannot be said that they suffice to establish it. The easy frangibility, the absence of evidence of cleavage, the hollowness, and the occasionally crust-like structure, though such as are common in pseudomorphic minerals, are not incompatible with the idiomorphism of these crystals; hollow and skeletal forms, indeed, are frequently a result of a hurried crystallisation, as is so well seen in the artificial crystals of bismuth and of sodium chloride. On the other hand, while the hardness indicates a difference of the material from native graphite, the sharpness, separateness, and completeness of the crystals, the brightness of the faces, the delicacy of the acicular projections, and especially of the obtuse, almost flat, square pyramids on some of the faces, are sufficient to prove that the form has never had any other than its present tenant, and that we have here an allotropic condition of crystallised carbon distinct from both diamond and graphite. And we may add that both of the recognised crystallised forms of carbon have long been standing difficulties for the crystallographer; as already pointed out, crystals of graphite are rarely more than mere tables of which there is a controversy as to the crystalline system, and those of the diamond are so different in their geometrical characters from the crystals of every other known substance that it cannot be satisfactorily determined whether they are to be referred to a holo-symmetric or to a hemi-symmetric type.

If it had been conceivable that the above characters, and the occurrence in the interior of meteoric iron, are compatible with a change in the material since the first development of the crystalline form, it would have been more easy to imagine that the change has been one of molecular re-arrangement than of substitution, and that the crystals were originally cubes of diamond. In fact, the diamond, when in cubes, has faces not very unlike

* *American Journal of Science*, 1876, Ser. 3, vol. ii., p. 388.

† *Pogg. Ann.*, 1846, vol. lxxvii., p. 437.

‡ *Beschreibung und Eintheilung der Meteoriten*, 1864, p. 40 *Pogg. Ann.*, 1873, vol. cxlviii., p. 516.

§ *Chemical and Physical Geology*, 1854, vol. i., p. 33.

those of the Younegin crystals, and shows usually a similar bevelling of its edges by rounded faces of tetrakis-hexahedra. Or, again, it might be argued that during a hurried crystallisation of the carbon, the circumstances, though initially favourable to the formation of diamond, had finally only permitted of the existence of the carbon in a graphitic form.

The nature of the faces, the obtuse pyramid, the spherical growth, the acicular projections, and the parallel groups, are different, however, from anything ever met with in the diamond.

On examination of a large nodule of graphite from the Cocke (or Sevier) county iron, now in the British Museum collection, distinct graphitic crystals, cubo-octohedral in form, were found to be present.

As this kind of crystallised graphitic carbon is unknown among terrestrial minerals, and has so important a bearing on the formation of meteoric graphite, it may conveniently receive a distinctive name, and I therefore suggest the term *Cliftonite*—after Mr. R. B. Clifton, M.A., F.R.S., Professor of Physics at Oxford, who has long interested himself in the physical characters of minerals, and has given great encouragement to their study.—*Mineralogical Magazine*.

MISCELLANEOUS.

Central Institution for Chemical Education.—The Session of the Central Institution of the City and Guilds of London Institute will commence on October 2nd. The Clothworkers, Siemens', Mitchell, and Institute's Scholarships will be competed for at an Examination held on September 25th to 28th. The courses of instruction include Lectures on Mathematics, Engineering, Chemistry, and Physics, and Laboratory and Workshop practice.

The Chemical Laboratory of Wiesbaden.—In the summer term, 1888, there were 65 students on the books. Of these 45 were from Germany, 6 from Russia, 5 from North America, 3 from Italy, 2 from England, 2 from Sweden, 1 from Spain, 1 from Transvaal. Besides the Director, Geh. Hofrath Prof. Dr. R. Fresenius, there are engaged as teachers Prof. Dr. H. Fresenius, Dr. E. Borgmann, Dr. W. Fresenius, Dr. E. Hintz, Dr. med. F. Hueppe, and Architect T. Brahm. The assistants in the Instruction Laboratory are two in number, in the private Laboratory 15, and in the Versuchsstation 3. Besides the scientific researches, a great number of analyses were undertaken in the different departments of the Laboratory and the Versuchsstation on behalf of manufacture, trade, mining, agriculture, and hygiene.

NOTES AND QUERIES.

Refractory Stoppers.—The annoyance caused by the stopper becoming fixed in the neck is particularly liable to occur when the bottle contains caustic soda or potash, and after trying several ways to prevent it I hit upon the idea of coating the stopper with a thin film of paraffin wax, and this answers perfectly. The stopper of a bottle containing caustic soda which is in constant use, was treated in this manner about six months ago, and it has never given any trouble since, while before being waxed it was very troublesome in this respect. The idea may not be new, but as I have not seen it mentioned before, it may perhaps be useful to some of the readers of the *CHEMICAL NEWS*.—C. F. SEYMOUR ROTHWELL, Manchester, Sept. 3rd, 1888.

TO CORRESPONDENTS.

W. T. B. Ridge.—The information can be found in any good textbook of chemistry.

RESTORATION OF CHARRED WRITINGS.

Advertiser, Analytical Chemist, will dispose of his original process, by which the contents of Safes, often charred in extensive conflagrations, are restored to legibility. Large income from said process was secured by Advertiser after the great Chicago conflagration. — Address "Charred," *CHEMICAL NEWS* Office, Boy Court, Ludgate Hill, London, E.C.

CITY AND GUILDS OF LONDON INSTITUTE FOR THE ADVANCEMENT OF TECHNICAL EDUCATION. CENTRAL INSTITUTION, KENSINGTON.

The Courses of Lecture, Laboratory, and Workshop Instruction in MATHEMATICS, ENGINEERING, PHYSICS, and CHEMISTRY will recommence on Tuesday, October 2nd. A preliminary Examination for Students intending to take a complete Course of Instruction, or competing for Scholarships, will be held on September 25th to 28th.

Particulars of the complete Courses of Instruction suitable for ENGINEERS, ELECTRICAL ENGINEERS, and CHEMICAL ENGINEERS, and of the special or partial Courses may be obtained on application to the Principal Clerk, Central Institution, Exhibition Road, S.W.

JOHN WATNEY,
WALTER S. PRIDEAUX. } Hon. Secs.

Wanted, thoroughly experienced man to take charge of modern Gold Chlorination Plant; thorough practical knowledge of Concentration and Calcination absolutely necessary. —Address P. T., care of Messrs. Street and Co., Cornhill, E.C.

EMPTY PETROLEUM BARRELS.

RECEIVING WHARVES.

EAST.....BOW—ATLANTIC WHARF.
SOUTH.....OLD KENT ROAD, WESTERN WHARF.
RIVERMILLWALL, ST. ANDREWS WHARF.

Empties may also be delivered for our account to
PALMER'S WHARF, BETHNAL GREEN.
THAMES HAVEN PETROLEUM WHARF, THAMES HAVEN.

Or ANY RAILWAY DEPOT WITHIN 4 MILES OF THE ROYAL EXCHANGE, LONDON.

N.B.—All Empties delivered at a Railway Depot as above will be collected at our Expense. No charge to the Sender.

PRICE—If delivered at ATLANTIC, WESTERN, ST. ANDREW'S, or PALMER'S WHARF—10. per barrel above the price of the day at any other Wharf in London.

If delivered at a RAILWAY DEPOT—The same price as is paid by any other Receivers for delivery at their Wharf.

The same price paid for Russian as for American Empties.

Special Terms offered to Collectors and Costermongers.

Parcels of 15 barrels and over collected at sellers' own premises if within 4 miles of the Royal Exchange, London, and the same price given as would be paid by other receivers for delivery at their wharf.

NOTICE.—In the case of Empties sent for our account to a Railway Depot or to Palmer's or Thames Haven Wharf, please advise us when sending, and mark the barrels so that we can recognise them.

In the case of sellers wishing us to collect from their own premises, we shall be glad of two days' notice.

DEDUCTIONS FOR DAMAGE.—Broken Chimb or Stave 6d., broken Head 6d. to 1s. 6d. according to extent of damage.

THE KEROSENE COMPANY, LIMITED, 26, GREAT ST. HELENS, LONDON, E.C. IMPORTERS OF RUSSIAN PETROLEUM.

August 27th, 1888.

NOTICE.

The STUDENTS' NUMBER of the CHEMICAL NEWS will be published on Friday, September 21st. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the education, who have not yet forwarded the necessary information to our Office for publication in that Number, will confer a favour by sending it with the least possible delay.

Advertisements for this Number should reach the Office not later than Wednesday, the 19th prox.

KIRKHAM & CO.,

Chemical Engineers & Contractors for the Erection of Every Description of Chemical Plant.

ESTABLISHED 1857.

Everything connected with the **ERECTION OF ALKALI WORKS** a Speciality, including **VITRIOL** and **BLEACHING POWDER CHAMBERS**, **GAY-LUSSAC**, **GLOVER**, and **HYDROCHLORIC ACID TOWERS**; **WELDON PLANT**; **REVOLVER** and **HAND BLACK-ASH FURNACES**, etc., of the latest and most efficient pattern.

ST. PAUL'S SCHOOL.—An Examination
for filling up about Eighteen Vacancies on the Foundation will
be held on the 12th September next.—For information apply to the
Bursar, St. Paul's School, West Kensington.

ST. PAUL'S SCHOOL, West Kensington.

Candidates for Foundation Scholarships are particularly requested
to notice that the date of the Examination has been postponed from
September 5 to September 12 and following days.

Silicates of Soda and Potash in the state of
Soluble Glass, or in CONCENTRATED SOLUTION of first
quality, suited for the Manufacture of Soap and other purposes
supplied on best terms by W. GOSSAGE and Sons, Soap
Works, Widnes, Lancashire.

London Agents, COSTE and Co., 19 and 20, Water Lane, Tower
Street, E.C., who hold stock ready for delivery.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1503.

ADDRESS TO THE CHEMICAL SECTION OF THE BRITISH ASSOCIATION.*

By Professor WILLIAM A. TILDEN, D.Sc. Lond., F.R.S., F.C.S.,
President of the Section.

A PART of the duty which devolves upon the President of a Section of the British Association consists in delivering an address, and the knowledge that a pretty full liberty of choice is permitted in regard to the selection of a subject is the only source of comfort which serves to alleviate the onerous nature of the task.

It seemed to me that the time is gone by when an attempt to review progress over the whole field of chemical science is likely to be useful or even possible, and an account of what is being done within the narrow limits of those parts of the science to which I have been able to give special attention would be ill-adapted to the character of a speech addressed to the members of the Section collectively. The fact that at the last meeting of the Association a Committee was appointed to inquire into the methods at present adopted for teaching chemistry suggested that, as I had not been able to accept an invitation to join this Committee, I might make use of this opportunity for contributing to the discussion. The first report of the Committee will be received with much interest by the Section. As might be expected, it embodies the expression of many varieties of opinion.

The existence of chemistry as a department of science, not merely requiring the observation of facts that are to be made useful, but seeking in the accumulated stores of observation to discover law, is a thing of comparatively recent growth. How chemistry arose out of alchemy I need not remind you, but the connection between the study of chemistry and that of medicine, and the maintenance of this connection down to even the present generation, is illustrated by the fact that a large number of men who have become eminent as chemists began their career in the surgery or the pharmacy. Black, Davy, Berzelius, Wollaston, Wöhler, Wurtz, Andrews, and W. A. Miller began by the study of medicine, whilst Scheele, H. Rose, and the great names of Liebig and Dumas are to be found in the long roll of those who received their earliest notions of chemistry in the pharmaceutical laboratory. Chemistry has been gradually emancipated from these associations with enormous advantage to both sides. So long as technical purposes alone were held in view a scientific chemistry could not exist, but no sooner did the study take an independent form and direction than multitudes of useful applications of the facts discovered became apparent.

It is only within a comparatively few years, however, that universities, in this country at least, have ceased to deal with chemistry as a kind of poor relation or humble follower of medicine, and have permitted her to emerge from the cellars of a museum or school of anatomy, and have given her a commodious dwelling in the fair light of day.

In the old time such instruction in chemistry as was given in the universities and mining or technical schools seems to have taken the form of lectures read by the Professor, and access to a laboratory for practical manipulation seems to have been a high privilege accorded only under exceptional circumstances to the few. We are told, for example, that when Liebig went to Paris in 1823 he applied to Gay-Lussac for practical instruction at first

without success, and that admission to the laboratory of the Ecole Polytechnique was ultimately granted him only through the intervention of Von Humboldt.

In a great many cases the student of chemistry must have been almost entirely dependent upon private study, though books were scarce and materials more costly than now. Davy, for example, seems to have had no instruction whatever previous to his appointment as assistant to Dr. Beddoes at the Pneumatic Institute at Bristol.

Doubtless, therefore, the recollection of his own early difficulties when seeking instruction contributed largely to influence Liebig in the establishment of the laboratory in the University of Giessen, and in the adoption of the principles which guided his teaching there. For the first time in the history of chemistry students met not merely to listen to the discourse of a professor concerning his own experiments and conclusions, but to examine for themselves the basis of the theories taught, to learn the processes of analysis, and by independent investigation to extend the boundaries of existing knowledge.

The fame of the new school spread fast and far, and soon men from every part of the civilised world assembled to share in the advantages offered. The influence of the new method can be estimated when we reflect that nearly all the now passing generation of chemists in England and America obtained the greater part of their training in Liebig's laboratory; and as a large number of them have been teachers, it may be assumed that they transplanted into their own countries the methods they had learnt from the great German master.

It was not till 1846, long after the school at Giessen had risen into fame, that in England a sense of our deficiencies in respect to provision for teaching chemistry was felt strongly enough to lead to the establishment of a college of chemistry. At that time the Professor of Chemistry at Oxford was also Professor of Botany. At Cambridge it was thought praise and boast enough that the occupant of the chair of chemistry had, during more than thirty years, frequently resided at the University and every year gave a course of lectures. The Jacksonian professorship was not then, as now, in the possession of a chemist. University College, London, had at this period a very distinguished man in the chair of chemistry, but it was only in 1848 that a commodious laboratory was provided by public subscription, raised in commemoration of the services of Dr. Birkbeck in promoting popular education. In that year Fownes was appointed to co-operate with Graham in the work of teaching, though his premature death soon after left but little time for the fulfilment of the rich promise of his earlier years. At Manchester John Owens had died in 1846, leaving the bulk of his estate for the purpose of establishing a university in Manchester, but as yet the Owens College was not.

The foundation of the College of Chemistry in 1846 was therefore an event of supreme importance in the history of chemical teaching in this country; and though at the time some dissatisfaction was expressed at the choice of the professor selected to direct the work, who, though a distinguished pupil of Liebig, was not an Englishman, all British chemists now concur in believing the choice to have been a most fortunate one. The great majority of my contemporaries having begun, continued, or ended their studies in Oxford Street, they and all who have come under Dr. Hofmann's teaching know how vast was his capacity for work and how marvellous was the power he possessed of communicating his own enthusiasm to his pupils.

Since the time of which I have been speaking the means of instruction in science in England have multiplied enormously. In University College, London, founded in 1828, and in Owens College, Manchester, founded in 1851, not only have chairs of chemistry existed from the first, but they have been occupied by a succession of chemists of the highest eminence. But long after 1846 the whole of the serious teaching of scientific chemistry was accom-

* Read Thursday, September 6, 1888.

plished at the College of Chemistry, and it was nigh upon twenty years before the Manchester school began to attract considerable notice.

In 1872-3 the movement set in which has resulted in the erection of colleges for higher instruction at a number of important English and Welsh towns. These, together with the pre-existent Queen's Colleges in Ireland and the Universities of more ancient foundation in the three kingdoms, are for the most part provided with pretty good laboratories and a competent staff. We have also the Normal School of Science and the Institute raised by the City and Guilds of London at South Kensington, and its Associate College at Finsbury. England is therefore at the present time as well provided with *places* of instruction for the study of chemistry as any country in the world.

And a very large proportion of the professors or heads of the chemical schools in the colleges and universities of the United Kingdom have shown by their own activity in research that they are qualified to give instruction of the highest kind, and are ready to train young chemists in the art as well as in the theory of their subject.

It is therefore no longer true that a student desiring to become a scientific chemist must needs choose between a single institution in London and another in Manchester, or must seek the instruction which he cannot get at home in the laboratory of a foreign university. As an element in a liberal education, the position of chemistry is also considerably in advance of what it was twenty years ago.

It is nevertheless true that increased opportunities for study, a considerable supply of capable teachers, and an enormous body of students have not produced such an amount of original investigation, or even of accurate analytical work, as might reasonably be expected. A full and complete explanation of all the influences which contribute to this result would be difficult; but I think the apparent inactivity of the chemical schools in this country is not generally the fault of the professors, but is chargeable in the main to the ignorance and partly to the indifference of the public. There exists as yet no intelligent feeling in favour of learning, nor indeed in favour of any sort of education, unless there is expectation of direct returns in the form of obvious practical results. It is this which animates the present popular movement in favour of so-called "technical" education. That part of the attention of the nation which can be spared from the contemplation of Irish affairs is concentrated upon the problem of how to make every little boy learn the rudiments of chemistry, whether he likes it or not, whilst there are comparatively few people interested in the question of how to provide means and instruction for those who are capable and desirous of attaining to a mastery of the subject. Moreover, the public have not yet grasped this truth, that, so far as chemistry is concerned, it is of very little consequence to the great metallurgical and chemical industries whether the workpeople do or do not know a little chemistry, though it is important that they should be intelligent enough to obey orders. What is wanted is that every manufacturer and manager should himself be an accomplished engineer and chemist, trained to observe, to reason, and to solve problems for himself.

In the case of chemistry this absence of sentiment in favour of concentration and thoroughness, and the demand for superficiality, if only it can be had wholesale, tells in a variety of ways. The governing bodies who control the various colleges and universities, and the public generally, cannot understand that good and useful work is being done unless it can be shown in the form of passes at examinations. Though I most firmly believe in the necessity for examinations serious mischief begins when they are regarded as the end itself, and not as mere incidents in the student's career towards the end, which should be knowledge.

In respect to chemistry this is the disadvantage which attends the operation of such a system as that of the Science and Art Department, or of any system under which

certificates in connection with individual subjects are granted on easy terms. Especial objection I also feel to such expressions as "advanced," used in reference to a particular stage, so commonly misunderstood as they are by the student and his friends, and operating against his further progress.

Reflected also upon the fact that there are only two or three colleges in this country which can boast of more than one professor of chemistry. In nearly all cases one man is called upon to discharge the duty of teaching classes, both elementary and advanced, in pure and applied chemistry, inorganic and organic, theoretical and practical. This is a kind of thing which kills specialism, and without specialists we can have not only no advance, but no efficient teaching of more than rudiments.

That teachers ought to engage in research at all is by no means clear to the public and to those representatives of the public who are charged with the administration of these new institutions. This was illustrated very painfully a few years ago by the conditions under which professors were engaged at a certain college founded, according to the declaration of its promoters, "by the people for the people," wherein it was announced in round terms that original research was not wanted, as the college was "for the good of the many and not for the advantage of the few." This example of ignorance is only remarkable by reason of its audacity. Probably many people hold a similar view, though few are bold enough to declare it.

Without going far into the discussion of the general question, which is a large one, I may perhaps be allowed to offer a few remarks for the consideration of any of my audience who may perchance incline towards that opinion.

It is only when a teacher occupies himself with research that the most complete guarantee is given that he is interested in his subject, and that he is a learner. A popular mistake consists in regarding a professor as a living embodiment of science—complete, infallible, mysterious; whereas in truth he is, or ought to be, only a senior student who devotes the greater part of his time to extending and consolidating his own knowledge for the benefit of those who come to learn of him, not only what lies within the boundaries of the known, but how to penetrate into the far greater region of the unknown. Moreover, the man who has no intellectual independence and simply accepts other people's views without challenge is pretty certain to make the stock of knowledge with which he sets out in life do service to the end. That one may be fitted to form a sound judgment concerning new theories, he must be familiar with the methods by which progress is accomplished. The work of investigation then re-acts beneficially upon the work of teaching; that is why teachers should be encouraged, nay even required to investigate, and not because their discoveries may haply prove to be practically useful.

Of course it may be said that there have been distinguished investigators who could not teach, but the converse is not true; every teacher who has attained to eminence as a teacher, who has drawn men after him, who has founded a school of thought, and has left his mark upon his generation, has been an industrious worker in research of some kind. All teachers cannot be expected to reach the same high standard, but this is the ideal after which all must strive, or fail utterly.

The fact that there is as yet little demand among schoolmasters for high attainments in chemistry is another reason why so little is accomplished in the chemical schools. Here again the public is really to blame. It is disgraceful that in all classes of schools, even where chemistry is supposed to be taught, there are but few places where serious employment is found for the well-trained chemist. I could point to several schools which claim the position of first-rate, where chemistry is taught by masters who have never studied the subject at all, but who are, I suppose, allowed the traditional "ten

minutes' start" with the book. Would the head-masters of such places dare to employ a person to teach mathematics who did not know the four first rules of arithmetic, or another to teach Latin who had not even got through the accidence? I fancy not. This, however, is, without exaggeration, the exact parallel of the position in which chemistry is placed in the majority of schools. I have heard the excuse that there is a lack of competent teachers. Of course the demand and the supply will react upon each other. When you offer a reasonable stipend, reasonable accommodation for teaching effectively, reasonable leisure for the master's own studies, and a position on the staff not inferior to that of the classical and mathematical masters, I believe that then, but not till then, there will be as many good school teachers of chemistry as there are of other subjects.

I could point to other prominent schools where the chemistry and other branches of science are taught by a peripatetic South Kensington teacher, who arrives weekly with his box of tricks. Not long ago I was invited to distribute the prizes given in connection with the evening classes in a town not far from Birmingham, and I took the opportunity of advising the teachers present on the occasion to read. One of them said to me afterwards, "When do you suppose I can read? I am engaged in going round to my schools from nine in the morning till ten at night." People of this kind do the greater part of the so-called science teaching sustained by the Science and Art Department, and the worthy town councillors and committees who employ them think that these are the people who are going to help the British manufacturer in his struggle against foreign competition under the guidance of the highly-trained chemists from the German universities. This would be ludicrous if it were not so very serious.

There is an opportunity at the present time of correcting some of these mistakes, but no advantage is being taken of it. I refer now to the "technical schools" which are springing up everywhere. There may be a few competent teachers of chemistry employed in some of them, but I find it difficult to think of many examples. The sort of person who is put in charge of these places is usually a schoolmaster, who is allowed, sometimes even after his appointment, to get a short course of qualitative analysis in order to enable him to obtain a certificate which will entitle him to earn grants from the Science and Art Department.

And manufacturers are much to blame. Instead of employing trained chemists the greater number of those who want chemical assistance are satisfied to engage the services of boys who have been to an evening class for a winter or two.

The difficulty of finding a satisfactory career in connection with the subject also accounts for the fact which I fear must be admitted, that chemistry does not attract its due share of the intellect of the nation. Clever young men can usually do better at the law, in medicine, or in commerce, than in teaching chemistry or in manufactures in which chemical skill is applicable. So badly educated are many of the young men who commence the study with professional objects in view, that it is quite impossible to teach them anything beyond routine analysis, if so much.

I heard lately from a friend of mine a story of a young groom in his employ who cannot read or write—and who declines to be taught to read on the ground that, considering himself pretty smart, he is afraid that "learning might dull him." This idea seems to be rather prevalent among certain classes of people, but I can assure those who wish to be chemists that some familiarity with the rule of three, and such a command of English as will enable them to understand words of more than one syllable, will be no obstacle to the acquisition of chemical knowledge.

Three years has hitherto been regarded as the normal period for study. The question arises, can a young man, previously well educated, expect to become an accom-

plished chemist, competent to apply his knowledge usefully, by giving the whole of his time to study during *three* years? I believe not.

By reason of the enormous development of the science the position of the student of chemistry is nowadays very different from what it was thirty years ago. Since that time we have not only got a few new elements, a matter of small importance in itself, but new views of the nature of the elements and of their mutual relations. This could hardly have come about but for the recognition of the law of Avogadro as a fundamental principle, upon which we rely as the ultimate criterion by which the true distinction between so-called equivalent weights and molecular ratios has been established. By the gradual evolution of ideas having reference successively to the electro-chemical relations of elements and compounds, the theory of types, and atomicity or valency, we have arrived at notions of chemical constitution based upon the hypothesis of the orderly linking together of atoms. Thirty years ago isomerism had scarcely attracted notice, and carbon compounds were only just beginning to be arranged in homologous series. The general use at the present day of the language of the molecular kinetic theory shows how deeply this theory influences our ideas of the internal constitution of matter. Within the period referred to, dissociation has been studied, and a vast body of thermo-chemical data have been accumulated. And although the larger portion of the results of this work still await interpretation, dynamical ideas of chemical action are now generally accepted. We have also new methods of investigation, including spectroscopic analysis with all its vast train of results.

When I began chemistry many of these subjects and others had not been heard of. Of course we had our difficulties, and I well remember the puzzles met with in the endeavour to refer compounds to their appropriate types, also the consternation caused in the student's mind and the confusion in his note-book by the successive changes in the atomic weights of carbon, oxygen, sulphur, and the metals. But on the whole there was much less to learn.

It has always been thought essential that a student of chemistry should have some knowledge of physics. It is now more than ever necessary that this knowledge should be extensive, sound, and based upon a good foundation of mathematics. Thirty years ago a hundred pages of Pownes contained all that was thought necessary, but no one nowadays could be satisfied with that. It is now asserted that a young chemist who expects to find a career in industrial chemistry should also have learnt drawing, and more important still that he should have a good general knowledge of mechanics, steam, and building construction. I suppose everyone will agree in adding French and especially German. You see how the requirements expand.

The inference from all this is that it now takes longer to make a chemist than formerly. This is a point of considerable practical importance.

My estimate that a well-educated and intelligent young man will now require five years for the study of chemistry and accessory subjects before he is likely to be of much use will not appear extravagant.

Here one may remark that in order to become a chemist it is before all things necessary to study chemistry. If the greater part of a student's time is to be taken up with other things it is not very clear how this is to be done.

A reform all round is wanted. The mathematics, modern languages, and drawing properly belong to the antecedent school period, and I believe the Institute of Chemistry would greatly promote the interests of the profession if it would impose upon candidates for the Associateship not only a three years' course of training with an examination in practical chemistry at the end, but a severe examination in mathematics, in the English, French, and German languages, and perhaps drawing before matriculation or registration.

A consideration of the present position of the student

of chemistry leads naturally to a review of the methods of teaching the subject. Speaking broadly, I suppose nearly all professional chemists who have had the advantage of systematic training have, up to the present time, passed through very much the same kind of course. This consists, as everybody knows, very largely of analytical work, qualitative and quantitative, preceded or followed by the preparation of a number of definite chemical compounds, besides practice in certain very necessary physical determinations, *e.g.*, relative density of solids, liquids, and gases, melting points, boiling points, and so forth. There seems now to be a disposition in some quarters to depart from this time-honoured curriculum in favour of a course in which the student is early engaged in some semblance of investigation, and in which he is encouraged to attack difficult problems, which from their fundamental importance offer considerable temptation. I venture to express a hope that this will not be carried too far. Already we are in danger of losing the art of accurate analysis. One constantly meets with young chemists who are ready enough to discuss the constitution of benzene, but who cannot make a reliable combustion. And according to my own experience attempts at research among inexperienced chemists become abortive more frequently in consequence of deficient analytical skill than from any other cause.

One modification I should gladly see generally adopted. I think an unnecessary amount of time is often spent upon qualitative mineral analysis, and an acquaintance with the properties of common and important carbon compounds ought to be acquired at an early stage. Quantitative work might with advantage be taken up much sooner than usual. By that, however, I mean serious work in which good methods are used and every effort made to secure accuracy. I do not believe in the use of rough methods, because they are easy; the use of such leads the student to be satisfied with approximations, which after all he will learn soon enough is all that is possible to man. I am very glad to know that I have the support of one of my predecessors in this chair (Sir Henry Roscoe), whose opinion will carry far greater weight than mine in deprecating premature efforts to engage students in research.*

But though it does not appear to me to be wise to encourage beginners, without sufficient experience or manipulative skill, to attempt original work, one of the best possible exercises preparatory to original work is to select suitable memoirs, and not only to read them but to work conscientiously through the whole of the preparations and analyses described, following the instructions given. Many of Dr. Hofmann's papers afford excellent examples. So also do the writings of Dr. Perkin and Dr. Frankland, besides those of many other chemists which could easily be selected by the teacher.

An intelligent student, possessing the requisite preliminary knowledge, would obtain much instruction by repeating the work contained in such papers as the following, for example:—Emerson Reynolds on the missing Sulphur Urea (*Fourn. Chem. Soc.*, 1869—i.); Fittig and Tollens on the Synthesis of Hydrocarbons of the Benzol Series (*Liebigs Annalen*, 1864, cxxxi., 303); L. Claisen and Pupils on the introduction of Acid Radicles into Ketones, &c. (*Berichte*, xx.); Lawson and Collie on the Action of Heat on Salts of Tetramethyl-Ammonium (*Fourn. Chem. Soc.*, June, 1888); Thorpe and Hambly on Manganic Trioxide (*Fourn. Chem. Soc.*, March, 1888); besides many others, including papers on analytical processes. To such as these there might subsequently be added the determination of an atomic weight on the model of one of the best masters, as a discipline which could not fail to be impressive, and full of instruction.

When chemistry is taught, not with professional or technical objects in view, but for the sake of educational effects, as an ingredient in a liberal education, the primary object is to make the pupil observe and think. But with

young students it is very important to proceed slowly, for chemistry is really a very difficult subject at first, owing to the variety of strange materials with uncouth names. To reason from particulars to generals is for the unpractised always a difficult process, and in chemistry this is specially the case. With young students it is, in my experience, preferable to adopt a somewhat dogmatic style, which should of course be exchanged for a more cautious one as the pupil proceeds.

Thus the law of Avogadro can only be given at first as a recognised physical law, without much explanation, since the full apprehension of the evidence upon which it rests can only be secured at a late stage of the learner's progress. There is of course great advantage in the use of an inductive method if only it is employed judiciously. Otherwise the result is only confusion.

A number of papers, pamphlets, and text-books have lately appeared, professing to teach the principles of the science practically and by new methods. Most of these turn out, upon inspection, to be very old methods indeed, but there is a small residue of distinctly original character which are sure to attract, as they deserve, considerable attention. The systems I refer to provide a series of problems which the pupils are called upon to solve. According to this plan the student is not allowed peaceably to examine the properties of oxygen or sulphur which he now sees for the first time. He must weigh, and measure, and observe, and then infer. All this coming at once upon the head of a beginner seems to me to be well fitted to drive him to despair.

I well remember the first experiment in chemistry I ever made. It consisted in dissolving zinc in diluted sulphuric acid in an evaporating dish, lighting with a match the bubbles of hydrogen as they rose, and afterwards leaving the solution to crystallise. I was about sixteen, and the bubbles of gas as well as the crystals I afterwards got interested me very much. If at that time I had been made to weigh the zinc and acid, and measure the hydrogen with the object of answering some question about the composition of zinc and hydrogen sulphates, I should have been pretty much in the position of a boy ignorant of geometry shut up with the propositions of Euclid and ordered to give the demonstrations.

I think when we recall such a fact as that Priestly, who discovered oxygen in 1774, failed to the end of his days to understand the process of combustion, and actually wrote, in 1800, a pamphlet in defence of "phlogiston," we ought not to be surprised when young people, though born a century later, fail to perceive at once the full significance of facts to which they are introduced for the first time. At the outset you cannot reasonably expect a young student both to observe accurately and infer justly. These two things must be kept separate at first, and for this reason among others I believe that attempts to make young students verify for themselves the fundamental propositions of chemistry will not be successful. One has only to trace the origin of one's own convictions in reference to any important fact or principle to perceive that they very seldom spring into existence suddenly, but almost always commence in vagueness and hesitation, acquiring consistency and solidity only as the result of accumulated experience.

I will not pretend to determine what may be included within the wide circle of the functions of the British Association; but I think I cannot be mistaken in assuming that the advancement of science is dependent in no small degree upon the provision for the efficient teaching of science. I have traced an outline of what has been done in the past, and have endeavoured to show in what respects I think we are deficient at the present time. No matter how ardent may be the aspirations, how earnest the endeavours of the few, progress will be slow unless they are sustained by the sympathy of the many. On one principle the public must surely insist, that only those shall be allowed to teach who know.

APPARATUS FOR GENERATING SULPHURETTED HYDROGEN OR HYDROGEN GAS.

By JOHN H. J. DAGGER, F.I.C., F.C.S.

THIS form of apparatus, which has been in use for some time past in my laboratory, consists of a glass vessel, A, containing dilute HCl, and is connected with the generator, B, by a flexible caoutchouc tube which may be any convenient length.

The lower tubulure of B is closed by a caoutchouc stopper, through which passes a piece of glass tubing about 8 c.m. long; the flexible tube is slipped over the end of this and bound by a few turns of fine platinum wire. The lower part of B is filled with large pieces of glass or small glass marbles to about $\frac{1}{4}$ inch above the

A cheap form of the apparatus may be readily constructed with two lamp glasses.

The Phoenix Smelting Works, Neath.

ELECTROLYTIC METHOD OF LIQUEFYING GASES.

By H. N. WARREN, Research Analyst.

THE usual method of liquefying a gas such, for instance, as chlorine, sulphur dioxide, &c., is, as is well known, prepared either by the action its own pressure exhorts when evolved in a confined space, or by intense cold, or thirdly by a combination of both. A brief description of the electrolytic method will therefore suffice to explain

end of the acid tube—above this layer is the FeS or granulated Zn, as the case may be, in pieces small enough to pass through the upper tubulure of B, which is closed by a caoutchouc stopper, through which passes the delivery tube, which may be connected with the ordinary washing apparatus.

The vessels, A and B, are supported by wooden forks, a, b, c, d, arranged at different heights, and fixed to the side of the H₂S cupboard—for lecture purposes suitable stands with screw clamps to admit of either vessel being raised or lowered would be used.

By altering the levels the flow of gas can be stopped or regulated. By simply disconnecting the delivery tube the bulbs may be removed together and cleansed or recharged in a few minutes.

the strong analogy that exists with respect to both methods, save that at present the latter method is better adapted when a compound gas is desired, such, for instance, as HCl, &c. The apparatus employed consists solely of a stout glass combustion-tube, bent at right angles, and closed at either extremity, the longer limb containing two small platinum plates fused into the extremity of the tube, the bend of the tube containing a small plug of asbestos, soaked or saturated with strong H₂SO₄ for the purpose of retaining moisture. For the preparation of liquid HCl a sufficiency of a strong solution of HCl is first introduced, covering the platinum plates, and the asbestos plug inserted in the bend of the tube. The other extremity, being accurately sealed, is introduced into a freezing mixture of ice and salt. To

the outer extremity of the platinum plates, which should, for convenience sake, terminate in the form of wire, is connected a voltaic battery capable of quickly decomposing the acid. Large volumes of hydrogen gas, together with chlorine gas, are at once evolved, and becoming confined in the smaller end of the tube, aided by the low temperature produced by means of the freezing mixture, the gaseous HCl rapidly assumes the liquid form, the liquid thus produced being generally possessed of a decided yellow tint, due to the presence of free chlorine. If now the tube and its contents are withdrawn from the freezing mixture and the circuit discontinued, the liquid gas is quickly re-absorbed by the water, forming the original solution, which experiment may again be performed as before; a number of the various other compound gases may also likewise be obtained.

An interesting reaction is also afforded when acidified water is substituted in place of the HCl solution, the condensing part of the apparatus being also provided with a very thin platinum plate, to the surface of which is attached some platinum black. On connection with the batteries being thus completed, the usual decomposition of the water takes place, and the liberated gases, owing to the intense pressure they are exposed to, together with the surface action that is afforded, and peculiar to that metal, explode at intervals, each time generating small quantities of water, which was found, on examination, to contain large quantities of H_2O_2 , besides retaining a peculiar ozonised odour.

The above reaction may be made altogether more striking, and affords an excellent lecture experiment when a small quantity of water containing a few drops of chromic acid, to which a quantity of ether has been added, sufficient to form a layer on the surface, the ether quickly assuming a deep blue colour, due to its absorption of the well-known blue oxide of chromium. By substitution of the acidified water various other compounds, such, for instance, as acetylene, may be readily formed. For the liquefaction of hydrogen and oxygen gas, a modified wrought-iron condenser has been constructed, but hitherto the results have been only partially successful, although, in more than one instance, hydrogen gas has been decidedly liquefied.

NOTE ON BARIUM SULPHITE.

By E. RATTENBURY HODGES.

MANY text-books state that barium sulphite is soluble in hydrochloric acid. Having occasion recently to test a sample of sodium sulphite for traces of the sulphate, with barium chloride in the usual way. I found the precipitate did not dissolve in HCl. This result evidently pointed to the presence of a sulphate, but still it seemed worth while to try the point in other ways.

(1). To a solution of $BaCl_2$ I added a solution of sulphur dioxide, and obtained a white precipitate, also insoluble in HCl, whether dilute or strong.

On boiling, the precipitate remained undissolved; but in this case it seemed likely that some sulphuric acid had come over with the sulphur dioxide (for the latter had been prepared by reducing H_2SO_4 with copper), and that the test was therefore unreliable.

(2). Sulphur dioxide gas, obtained by warming crystals of sodium thiosulphate with strong HCl, was passed into a fresh solution of barium chloride, and the result was the same, a precipitate of barium sulphite insoluble in HCl.

(3). Another sample of sodium sulphite in crystals was warmed with HCl, and the gas thus evolved was passed into $BaCl_2$. In this case also, on the addition of HCl, the precipitate did not dissolve.

All the precipitates which were left in the presence of

HCl remained undissolved after ten hours' standing. Both samples of sodium sulphite gave an alkaline reaction with test-paper.

Suspecting now the hydrochloric acid, I tested it for sulphuric acid, but found no traces.

The above results make it appear tolerably conclusive that barium sulphite is not soluble in hydrochloric acid, the chemical text-books notwithstanding.

Nottingham, August 28, 1888.

DETERMINATION OF TRACES OF ARSENIC IN TISSUES, YARNS, AND PAPER-HANGINGS.

By R. FRESENIUS and E. HINTZ.

In endeavouring to convert the so-called Swedish process for the examination of arsenical textile substances into a quantitative method, the authors have proceeded as follows, with good results.

Twenty-five grms. of the tissue in question were cut up and introduced into a tubulated retort of Bohemian glass holding about $\frac{1}{2}$ litre, and covered with $\frac{1}{4}$ litre of hydrochloric acid of sp. gr. 1.19. The neck of the retort was then bent at an obtuse angle, and it was placed so that the part of the neck next the body was turned obliquely upwards, and the other part obliquely downwards. The latter part was connected with a condenser, the tube of which led air-tight into a tubulated receiver of 700 to 800 c.c. The receiver was charged with 200 c.c. water and was plunged in a larger vessel of water in order to keep it cool. A Peligot tube containing a little water was also connected with the receiver by its tubulure.

After thus digesting the material for one hour, 5 c.c. of an aqueous solution of ferrous chloride (saturated in the cold) were introduced into the retort; the glass stopper was fixed air-tight in the tubulure by means of vaseline, and a gentle heat was applied by means of a Maste lamp. After the excess of hydrochloric acid gas has passed over the temperature is raised so that the liquid boils, which is continued until strong frothing puts a stop to the distillation. More than two-thirds of the liquid in the retort could generally be distilled over. When cold, 100 c.c. of hydrochloric acid at 1.19 are added to the contents of the retort and distilled off as far as possible. In this second distillate only very trifling quantities of arsenic are present. Both the distillates, which are coloured brown by organic substances, are mixed with the contents of the Peligot tube, and diluted to 800 c.c. Into this liquid sulphuretted hydrogen is passed, warming gently at first, and afterwards in the cold, and it is let stand for twelve hours. The precipitate, along with arsenic sulphide, contains relatively much organic matter which must be eliminated. For this purpose the precipitate is collected upon an asbestos filter, prepared by placing asbestos in a funnel fitted with a glass cock. After the precipitate has been washed the cock of the funnel is closed and the precipitate in the funnel is treated with bromo-hydrochloric acid, prepared by dissolving bromine in hydrochloric acid of 1.19. The funnel must be covered with a glass plate. After this acid has acted for a sufficient time the cock of the funnel is opened and the solution is let flow down into the precipitation flask, to the sides of which some small portions of the precipitate often adhere. To avoid, as far as possible, dilution of the acid, the asbestos filter is previously washed with hydrochloric acid of 1.19. The liquid in the flask is mixed with an excess of ferrous chloride, and its contents are rinsed with hydrochloric acid as before into a smaller retort of a distillation apparatus otherwise similar to the above. The contents of the retort were then distilled off to a very small residue, so that in general a single distillation conveyed all the arsenic into the distillate. The contents of the receiver and of the Peligot tube, on re-treatment with sulphuretted hydrogen, yielded pure arsenic trisulphide. This was

collected upon a filter, dried at 110° , washed first with water, and then successively with absolute alcohol, carbon disulphide, and again with alcohol, in order to remove free sulphur. The whole is then weighed after drying at 110° . All the reagents and the glass vessels must be subjected to a blank experiment in order to prove the absence of arsenic.

The method is available for the examination of colouring-matters.—*Zeitschrift für Analytische Chemie* (vol. xxvii., p. 179).

SEPARATION OF LEAD AND BISMUTH.*

By HERMAN HERZOG, Jun.

THE author made a series of experiments testing the principal methods for separating lead from bismuth.

1. Equal parts of both metals in solution as nitrates were treated with a slight excess of sulphuric acid and then heated until all nitric acid had been expelled, after which the solution was evaporated to complete dryness. Then dilute sulphuric acid (1:10) was added and, after digestion, the residue was filtered and washed with dilute sulphuric acid. A series of ten experiments showed that from 1.97 per cent to 2.79 per cent of the bismuth remained with the lead—the mean of the ten experiments being equal to 2.51 per cent.

2. A similar solution was evaporated in a like manner until fumes of sulphuric acid went off copiously and the mass had changed into a solid cake. It was then treated with acid as before. Ten experiments showed that from 1.05 to 1.31 per cent of the bismuth (or a mean of 1.17 per cent) remained with the lead.

3. Similar solutions were evaporated as before until fibrous crystals of bismuth sulphate appeared and fumes of sulphuric acid began to be evolved—then diluted with water and dilute sulphuric acid, &c. In ten experiments only 0.19 to 0.41 per cent of the bismuth remained with the lead. (The mean was 0.28 per cent). The latter method is the one generally made use of in the laboratory of the University—however, in order to recover the small amount of bismuth the lead sulphate is dissolved in hot sodium hydrate, from which solution it is subsequently precipitated by sulphuric acid. The minute residue left behind is dissolved in dilute nitric acid, evaporated with an excess of sulphuric acid, filtered, washed, and the solution added to the main filtrate from the lead.

Nine series of five experiments each, which the author made, showed that the strength of the sulphuric acid used in washing was of great influence on the accuracy of the determinations. His results were:—

Strength of Acid.	Bi_2O_3 left in the PbSO_4 .	PbO found with Bi_2O_3 .
1:4	0.009	7.54
1:5	0.019	6.05
1:7	0.072	0.51
1:8	0.172	0.30
1:9	0.51	0.07
1:10	0.79	trace
1:15	1.11	"
1:25	2.91	"
water	3.21	0.13

Equal quantities of lead and bismuth were taken.

The addition of alcohol has proved to be of no advantage, and is recommended merely to remove the sulphuric acid from the lead sulphate precipitate after washing.

It was found that the addition of hydrochloric acid before precipitating the lead as sulphate is of no advantage; on the contrary, notwithstanding the greater solubility of the lead chloride, it is difficult to convert it into sulphate,

the precipitate being often more chloride than sulphate even after standing for one day. Then also the bismuth, when precipitated in the filtrate by ammonium carbonate, contains oxychloride which on ignition will cause some of the metal to volatilise.

Experiments made to separate bismuth from lead as oxychloride gave from 2 to 5 per cent of the lead with the bismuth; on re-dissolving and re-precipitating the bismuth contained only traces of lead.

The method of separating bismuth from lead as basic nitrate gave unsatisfactory results; with bismuth alone the average of ten analyses showed 99.89 per cent of bismuth (maximum loss being 0.23 per cent, minimum, 0.09 per cent). If in presence of lead the evaporation is not carried far enough, bismuth will go in solution, whilst if carried so far as to render it insoluble from 8 to 11 per cent of lead may be retained.

Liebig's method of precipitating bismuth by barium or calcium carbonate gave low results and was otherwise unsatisfactory.

In Ullgren's method of precipitating bismuth by metallic lead the excess of acid in the solution of the nitrates was removed by evaporation, after which the solution was supersaturated with acetic acid and a weighed strip of lead was kept immersed for twenty-four hours. The spongy bismuth was washed off, if necessary, removed with the aid of a feather, and collected in a weighed button of fusible alloy and weighed. The lead was determined either as a sulphate or chromate, and the amount lost by the lead strip deducted from the calculated amount. The following results were obtained:—

		Amount in Grms.	
		I.	II.
		Taken. Found.	Taken. Found.
Pb		0.5523—0.5531	0.5619—0.5621
Bi		0.2310—0.2314	0.1921—0.1922
		III.	IV.
		Taken. Found.	Taken. Found.
Pb		0.6310—0.6314	0.1020—0.1018
Bi		0.0820—0.0822	0.5200—0.5208

Abel and Field's method of adding copper hydrate, or basic copper nitrate, to the solution which was nearly neutralised with ammonium hydrate, and then warming, gave good results, although somewhat high in bismuth. In twenty determinations the maximum deviation was not over 0.20 per cent above the amount of bismuth taken, and this can be reduced to a minimum by repeating the operation. The principal difficulty lies in the separation of the copper oxide from the bismuth oxide by ammonium hydrate, which should be repeated; the lead may be separated from the copper by ammonium carbonate or by precipitating it from an acetic acid solution as chromate.

The volumetric methods tried were all found to be more or less complicated and liable to error. The well-known chromate method gives very fair results. The method recommended by Haswell is to add sodium hydrate (or zinc oxide) to a nitric acid solution until a slight precipitate remains on standing; then to heat the solution to 60°C . in a porcelain vessel and to run potassium permanganate into it until the supernatant liquid remains pink after a few minutes standing. The results obtained were, on an average, about 0.7 per cent too high. Of all the other volumetric methods none gave even approximate results.

A method which has not been mentioned in any works on analytical chemistry, or in such journals as we have access to, has been worked out by the author and possesses sufficient merit to be put on record. It is based on the fact that in a neutral solution of a bismuth salt, the bismuth is precipitated as a basic acetate on boiling with sodium acetate.

The following manner of working gave the best results:—To the solution of the nitrates add sodium carbonate until a slight, but distinct, permanent, flocculent

precipitate is formed. Then shake and stir well, which will change it to a pearly crystalline compound which settles rapidly. If now, on adding another drop of sodium carbonate solution to the clear liquid, a precipitate is formed, the solution is ready for the addition of sodium acetate, which should be done in the cold. Then the solution should be boiled vigorously for $1\frac{1}{2}$ to 2 hours, filtered while hot, and washed with boiling water. Redissolve in dilute warm nitric acid and precipitate the bismuth by ammonium carbonate. The lead in the filtrate may be precipitated as chromate, or carbonate. The seven series of analyses that were made gave the above results.

NOTE ON THE ACTION OF ELECTRIC SPARKS ON MIXTURES OF NITRIC OXIDE WITH HYDROGEN AND OTHER INFLAMMABLE GASES.

By STEPHEN COOKE, F.C.S.

DAVY, in his "Researches on Nitrous Oxide," says:—"I passed a strong electric shock through equal parts of hydrogen and nitrous gas, confined by mercury in a detonating tube, but no inflammation and no perceptible diminution was produced." This statement, which I believe is quite correct, is still found in some of our works on Chemistry (e.g., Gmelin's). And nothing is said about the action of sparks on these gases mixed in other proportions, although Davy, a little further on, says:—"Perhaps, if I had tried many other different proportions of the gases, I should at last have discovered one in which they would have inflamed; for, as will be seen hereafter, nitrous oxide cannot be decomposed by the compound combustible gases, except definite quantities are employed." This paragraph to a great extent anticipates my experiments on this subject.

Henry, however, is less cautious, and in his "Elements of Chemistry" (9th Ed.), he makes the following statements (on what authority I do not know, but he seems to have experimented on the subject himself):—"It [nitric oxide] does not, however, explode with hydrogen in any proportion, nor with any of the varieties of carburetted hydrogen." (The italics are mine). And, again, "Nitrous gas does not, with hydrogen gas, afford a mixture that can be exploded by the electric spark." Henry's statements, as I shall show immediately, now need modification.

My own experience on this subject may not prove uninteresting. The first mixture used was equal volumes of nitric oxide and hydrogen, this being the most likely proportion to give any result. On passing sparks it was found that there was a pretty rapid contraction of the volume of gas, but no explosion. The gas left after all action was over was one-fourth the original volume. Evidently the change consisted in the reduction of nitric oxide by hydrogen—

I then took two volumes of nitric oxide and one volume of hydrogen, and on passing a spark through this mixture a pretty sharp explosion took place; white heavy fumes appeared in the tube, together with red fumes of nitric peroxide; the volume of the original gas diminished about 40 per cent, and the water in the eudiometer became strongly acid. This experiment was made over water. I then added to the residue a volume of hydrogen equal to that originally employed, and on passing a spark there was a prompt explosion. In this case no fumes (white or red) were formed.

Being busy at the time, I only made a few rough experiments, and at that time I thought the change in the first explosion consisted, for the most part, in reducing the nitric oxide to nitrous oxide, and this appeared somewhat probable, as the first explosion took place with some difficulty, sometimes requiring several sparks, while in the second stage the inflammation of the gases was easier, and the explosion appeared to have more force.

Returning to the subject some months afterwards, I was unable to get any result at all with similar mixtures of the gases. This appeared somewhat extraordinary, as I used pure nitric oxide in each case (prepared from FeSO_4 , KNO_3 , and H_2SO_4 , so as to avoid any trace of nitrous oxide), and everything the same, with the exception of a eudiometer. This new eudiometer had the wires approaching each other within $\frac{1}{8}$ of an inch, while the one formerly used was an older pattern (which had been broken in the interval), in which the wires were fully $\frac{1}{4}$ of an inch apart. Being unable to purchase one of the older kind, I made one with the wires about $\frac{1}{4}$ inch apart, and then the results were similar to those formerly obtained. Another experience may be mentioned here. During my experiments my own coil, giving an inch spark, got damaged, and being unwilling to wait for its repair, I borrowed another, giving a feeble spark. With this, however, no explosion could be got, although the spark would pass readily enough. This coil was then exchanged for one giving a 4-inch spark, and then there was no difficulty in getting an explosion every time, with the mixture already mentioned; and with the new coil a larger proportion of hydrogen could be used than with my own—a mixture of six volumes of hydrogen and ten volumes of nitric oxide exploding with this coil.

With a diminished pressure of 300 m.m. of mercury no explosion was obtained. On replacing the mercury by water the same mixture exploded readily. The carefully-dried gases exploded with equal ease to the undried gases.

Possibly with an increased pressure and greater spark, a higher proportion of hydrogen than that mentioned above might have been used.

As regards the explosion of nitric oxide and hydrogen, therefore, my experience may be summed up as follows:—

1. A spark from a feeble coil gives no explosion.
2. A spark from a larger coil gives no explosion if the wires are too close together.
3. No explosion takes place if the pressure is diminished to the extent of 300 m.m. of mercury—less than the atmospheric pressure.
4. No explosion takes place if the hydrogen has a greater proportion to the nitric oxide than 6 : 10.

In connection with 1 and 2, it may be interesting to note that Dixon, in a paper read before the Chemical

Society, about a year ago, obtained similar results with mixtures of oxygen and cyanogen gases, results which have been attributed to the greater distributing energy of the longer and more vigorous spark. The initial disturbance in these experiments not only determines the explosion, but influences to a considerable extent the resulting products.

We come now to the gases resulting from the explosions. I may state that my first experiments were made over mercury, and the gases resulting from the explosion were determined. The variation was found so great that only pretty general statements can be made. A number of my late experiments were made over water. A number of experiments were generally made with the same mixture—the gases being mixed in a small gasholder, and transferred to the eudiometer.

As illustrating the variation that may occur under like conditions, I may state that in making some experiments with a mixture of nitrous oxide and hydrogen in the proportion of 2 : 1, the residues were mixed and set aside for further examination. On adding the residues from the third explosion to the two first, red fumes were produced, showing that oxygen had been formed in the one case, and nitric oxide left undecomposed in the other.

Sometimes, owing to the greater initial disturbance of the spark, the flame passes down the tube with greater rapidity, and the explosion is more energetic than at other times. In such cases red fumes are produced, and oxygen is found in the residue.

If the eudiometer is too narrow the explosion may not travel more than a few inches from the wires, and a series of explosions may be got; but nitric oxide is left undecomposed.

Even in a wide tube the explosion may travel slowly down the tube, especially when near the bottom. In such cases nitric oxide may generally be found in the residual gases. With the apparatus mentioned, I have been able to obtain explosions when the volumes were—

H : NO :: 1 : 5.

With one volume of hydrogen to ten volumes of nitric oxide, no explosion could be obtained. The greatest amount of hydrogen with which I have been able to get an explosion is 6 vols. H to 10 vols. NO. The explosion then occurs with difficulty, and only when the larger coil I have mentioned is used. 2 vols. of H and 5 vols. of NO explode very readily. The greater number of experiments were made with mixtures of H : NO :: 2 : 5, and—

H : NO :: 1 : 5.

The gases produced by the explosion vary so considerably that a detailed account would be of little value. More than fifty experiments have been made, and in all but four or five free oxygen has been found in the residue; and this occurs with the smallest volume of hydrogen, as well as the greatest, depending more, I believe, on the force of the explosion and the temperature produced than the proportion of gases present. (For instance, thirteen experiments were made with the lowest amount of hydrogen, and in eleven of them oxygen was left). After explosion the residue left was, on the average, about 60 per cent, the extremes being 44 per cent and 71 per cent; and here, again, the proportion of gas left often depends more on the nature of the explosion than on the gases present. With two volumes of nitric oxide and one volume of hydrogen, the change may often be approximately represented by the following equation:—

The free oxygen is, however, always somewhat less than one-half the amount in the NO; in three cases the volume was determined and the lowest was 40.2 per cent, and the highest a little short of 45 per cent of the whole—a portion of the NO breaking up as follows:—

To me the most unlooked-for reaction in these experi-

ments is the production of free oxygen, especially when such a small volume of hydrogen is used.

I have already quoted Henry with reference to the action of hydrocarbons and nitrous oxide. Some hydrocarbons will, however, combine readily enough with NO if submitted to a suitable spark discharge, provided the volume be properly proportioned. Marsh-gas, especially, explodes more readily than hydrogen when the volume is not less than one-twentieth or greater than one-eighth of the nitric oxide used. The results show that all the carbon is oxidised to CO₂, and the residue in all my experiments contained free oxygen, this result being accounted for by the vigour of the explosion.

Sulphuretted hydrogen, when mixed with nitric oxide, can be readily exploded.

Carbonic oxide and nitric oxide did not, in any proportion, explode. There is a gradual combination, however, which may be represented by NO + CO = CO₂ + N.—*Glasgow Philosophical Transactions.*

OBITUARY.

PETER GRIESS.

WE regret having to announce that Mr. Peter Griess, well-known as a successful discoverer of coal-tar colours, died suddenly and unexpectedly on August 30th, whilst staying at Bournemouth. We hope to furnish further particulars in a subsequent issue.

CORRESPONDENCE.

ESTIMATION OF COPPER.

To the Editor of the Chemical News.

SIR,—In the ordinary burette assay of copper by cyanide of potassium the writer has long thought that the uncertainty of the method arose in great part from the use of ammonia. This induced him to try precipitating the copper by a solution of carbonate of soda, using a solution not too strong, but in such excess as to re-dissolve the precipitate in part, as seen by the blue colour of the solution. The cyanide solution is now added, until first the precipitate dissolves, and then until the blue colour of the copper solution is discharged.

I have obtained very close results from use of the above method, and shall be glad if they are confirmed by the experiments of others.

Mr. F. L. Merry has modified the original idea by adding sufficient tartaric acid to re-dissolve the precipitate caused by the carbonate of soda to a clear blue solution, and then buretting. He has had close results by this method.—I am, &c.,

J. L. DAVIES.

DR. PETERS'S AMERICAN METHODS OF COPPER SMELTING.

To the Editor of the Chemical News.

SIR,—I regret that I did not see the CHEMICAL NEWS of the 31st ultimo in time to reply to the letter of W. M. (CHEMICAL NEWS, vol. lvi., p. 108).

W. M. has made a serious mistake in stating that I took the concordant results of the electrolytic and iodide processes as evidence of proof of the accuracy of the latter, and a careful perusal of my article should have prevented him falling into such an error. As a matter of

fact the accuracy of the iodide process was proved by a series of experiments on known amounts of copper to which various impurities were added, and these experiments are given in detail in my paper (*Journal of the Society of Chemical Industry*, 1886, vol. v., pp. 52, 53), while on p. 54 I give my views and those of other analysts regarding the electrolytical method. Briefly, statements are made to the effect that bismuth, silver, and tin have been deposited with the copper, that ferric salts delay the precipitation, and, finally, the second of the propositions at the conclusion of my article runs as follows:—"That for the wet assay of copper, in ores and products generally, the iodide process (E. O. Brown's modification) is the most reliable and accurate, but that the electro-deposition method may also be used where it is desirable to have the results of two separate and distinct processes, it being noted that in certain cases other metals are deposited with the copper."

At the discussion on my paper the same doubts regarding the reliability of the electrolytical assay were expressed by other chemists, and in an article published in the *Mining Journal* (February 19th, 1887) I again refer to the subject in the following terms:—"My doubts regarding the reliability of the electrolytical process have been confirmed. Copper may in some cases be accurately determined from solutions of copper ores and products in acids, but the result is as a rule doubtful, and I find that most operators who use this method separate the copper as completely as possible from other metals, then depositing it from the purified solution by the electric current. The process so modified possesses no advantage over the iodide method, and any bismuth which may be present deposits with the copper and affects the accuracy of the results. These objections to the electrolytical method are confirmed by a footnote on p. 83 of Lunge and Hurter's "Alkali-Makers' Pocket-Book," where it is stated that the electrolytical method has not been adopted at the Duisberg Copper-Works, because copper precipitated the first time is not pure, and that two precipitations cause more trouble than the subsulphide method, which it is admitted requires an arbitrary correction for the bismuth and antimony present in pyrites."

I therefore submit that my statements regarding the relative value of the electrolytical and iodide processes have been consistent throughout, while, with regard to W. M.'s reference to the shrewdness and ability of American analysts, constituting a strong argument in favour of the electrolytical process, I am content to refer him to the extracts I have given from Dr. Peters's work, and to ask if the results there given would be considered satisfactory by any English analyst?—I am, &c.,

JAMES W. WESTMORELAND.

Leeds, September 8, 1888.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 8, August 20, 1888.

The Vapour Tension of Alcoholic Solutions.—F. M. Raoult.—The author concludes that for metallic salts as well as for organic bodies the relative decrease of the vapour tension produced by 1 mol. of the substance in 100 mols. of alcohol is approximately constant and is very close upon 0.0104.

Action of Micro-Organisms on Colouring-Matters.—J. Raulin.—The microbia of fermentation act by hydrogenation not merely upon extract of indigo. Logwood, orchil, and safranin are decolourised rapidly, and resume their

colour on exposure to the air. Certain azo-derivatives, such as the ponceau 3 R of Meister and Lucius, the orange 2 of Poirier, and Bordeaux red, are also rapidly decolourised, but do not resume their colour on aëration. Nicholson blue and imperial violet are decolourised in a few days, whilst magenta, cochineal, and the natural colouring-matter of wine resist for weeks.

The Relative Densities of Hydrogen and Oxygen.—Lord Rayleigh.—From the *Proceedings of the Royal Society*.

The General Reactions in the Preparation of Soda, Especially as to the Quantities of Heat Consumed.—G. Lunge.—The author finds that the Leblanc process to effect the separation of hydrochloric acid and sodium hydroxide in an aqueous solution employs fifteen times the quantity of the heat which is theoretically necessary for resolving sodium chloride into sodium and chlorine. Apparently the ammonia process is more economical in this respect, but it is only in appearance, since it furnishes neither free chlorine nor hydrochloric acid, and if we add to the process the manufacture of these latter products, the total consumption of fuel will certainly not be less than that of the Leblanc process. The energy required to effect the separation of sodium chloride into its elements is only a fraction of that which is consumed in the form of heat in the two processes at present in use. Hence it might be believed that the electrolytic decomposition might be effected by burning a much smaller quantity of coal sufficient to produce the needful sum of chemical energy in the form of electricity. Unfortunately this is not the case in practice. The useful work obtained by the intervention of electricity costs at present much more than the indirect means of decomposition now in use. This is owing to the losses of energy in the boilers, the steam-engine, the dynamo, to polarisation, and other causes not yet understood. The manufacture of soda by electricity, by the conversion of the current into chemical energy, is one of those problems which the future will certainly solve. Neither the Leblanc nor the Solvay process is industrially perfect. As regards the complete utilisation of the materials employed, the Solvay process is certainly more rational than that of Leblanc.

Natural Occurrence of Copper Antimonide.—Laist and Norton.—From the *CHEMICAL NEWS*.

Contribution to the Study of Grain and of Bread.—Dr. Michael Popow.—The possibility of nourishment entirely by bread may be realised if the equilibrium of nitrogen is preserved. The rye-bread of Russia, though fairly rich in nitrogenous matters, contains much cellulose and acid. The rye-bread of the country contains more cellulose than that of the towns, and is less nutritious.

On Chromium Mordants.—L. Whiteley.—The author's results have previously been published in *England*.

Characteristic Reactions of Artificial Colouring-matters.—Weingaertner and Zetter.—This useful memoir does not admit of abstraction.

New Antiseptics: Creoline.—V. Gerlach and R. Frühling.—Gerlach maintains that the germicide proper-

ties of creoline are incomparably more marked than those of phenol. Frühling declines to give an opinion on its antiseptic efficacy.

New Process for the Determination of Alcohol.—B. Roese.—This paper will be inserted in full.

Determination of Nitric Acid in Wine.—E. Pollak (*Chemiker Zeitung*).—One centigram. diphenylamine is dissolved in 10 c.c. of dilute sulphuric acid (1 part pure monohydrated acid and 3 parts water). It is diluted to 50 c.c. with strong sulphuric acid. For each assay 2 c.c. are poured into a small porcelain capsule. Meantime, the wine has been concentrated and decolourised by evaporation down to one-fifth over bone-black, previously washed and ignited. It is filtered through plugs of asbestos, as filter-paper almost always contains traces of nitric acid. The author takes two capsules of porcelain, each containing the reagent, and pours into each three to six drops of the wine prepared as above. If no blue colouration appears in ten minutes the absence of nitric acid is proved. Two out of twenty-five samples of pure wine gave a very feeble blue tint at the end of ten minutes. It thus appears that perfectly pure wines may contain traces of nitric acid, but in wines diluted with water the colour is much more intense and rapid.

MISCELLANEOUS.

British Association for the Advancement of Science.—The following are the names of the Officers and Committee of Section B (Chemical Science) of the Bath Meeting of the British Association:—

Vice-Presidents.—Prof. H. E. Armstrong, Ph.D., F.R.S.; J. H. Gladstone, Ph.D., F.R.S.; Prof. T. Sterry Hunt, F.R.S.; Prof. W. Odling, M.B., F.R.S.; W. H. Perkin, Ph.D., F.R.S.; Prof. J. Emerson Reynolds, M.A., F.R.S., M.R.I.A.; Sir H. E. Roscoe, B.A., LL.D., F.R.S.; W. I. Russell, Ph.D., F.R.S.; Prof. A. W. Williamson, LL.D., F.R.S.

Secretaries.—Prof. H. B. Dixon, M.A., F.R.S.; H. Forster Morley, M.A., D.Sc. (Recorder); R. E. Moyle, B.A.; Dr. W. W. J. Nicol, M.A., F.R.S.E.

Committee.—Sir F. A. Abel, F.R.S.; Prof. Roberts-Austen, F.R.S.; Dr. G. H. Bailey; Prof. P. P. Bedson; C. H. Bothamley; Sir I. Lowthian Bell, F.R.S.; P. Braham; Vaughan Cornish; Prof. Dunstan; T. Fairley; A. E. Fletcher; A. G. Vernon Harcourt, F.R.S.; Prof. E. Kinch; Prof. H. M'Leod, F.R.S.; Prof. R. Meldola, F.R.S.; M. M. Pattison Muir; Prof. Pickering; Dr. A. Richardson; Prof. Ramsay, F.R.S.; Dr. A. Scott; Prof. A. Smithells; Prof. H. L. Snape; H. W. Smith; John Spiller; Prof. C. M. Thomson; W. Thomson; Thomas Turner; V. H. Veley; G. Ward; R. Warington, F.R.S.

Delegate Member.—J. Brown.

The Papers brought before the Section were as follows:—

President's Address.

Report of the Committee on the Action of Light on the Hydracids in the presence of Oxygen.

Report of the Committee on the Bibliography of Solution.

Report of the Committee on the Properties of Solutions.

Report of the Committee on the Influence of Silicon on the Properties of Steel.

Report of the Committee on a Uniform System of Recording the Results of Water Analysis.

Prof. Sterry Hunt, F.R.S.—On the Study of Mineralogy.

Dr. G. Johnstone Stoney, F.R.S.—On the Logarithmic Law and its connection with the Atomic Weights.

Rev. A. Irving.—Notes on Dissociation.

J. E. Marsh.—On Camphoric Acid.

J. E. Marsh.—On Van't Hoff's Hypothesis and the Constitution of Benzene.

Discussion on the Chemical Problems presented by Living Bodies, opened by **Prof. Michael Foster, F.R.S.**

Dr. Alex. Scott.—The Atomic Weight of Oxygen.

Prof. H. B. Dixon and H. W. Smith.—The incompleteness of Combustion in Explosions.

Dr. W. W. J. Nicol.—A new Gas Analysis Apparatus.

Dr. W. Bott.—The Determination of Vapour Densities at High Temperatures and under Reduced Pressure.

Prof. P. P. Bedson.—Exhibition of a Photograph of a Hydrogen and Chlorine Bulb, produced by the Flash of Light which caused its Explosion.

J. Joly, M.A.—On the Formation of Crystals of Calcium Oxide and Magnesium Oxide in the Oxyhydrogen Flame.

The Report of the Committee on the Teaching of Chemistry.

Rev. A. Irving.—Chemistry as a School Subject.

Discussion on Valency, opened by **Prof. H. E. Armstrong, F.R.S.**

Prof. R. Meldola, F.R.S.—Evidence of the Quantivalence of Oxygen derived from the study of the Azonaphthol Compounds.

Prof. Sterry Hunt, F.R.S.—Theory of Solution.

A. P. Laurie.—The Composition of Copper-Tin Alloys.

John Spiller.—Analysis of Ancient Mortar from the Roman Wall of London.

V. H. Veley.—Action of Acids on Copper.

Fred. Bale.—Recovery of Ammonia and Chlorine in the Ammonia-Soda Process.

Report of the Committee on Isomeric Naphthalene Derivatives.

Dr. J. H. Gladstone and W. J. Hibbert.—Note on Molecular Weight of Caoutchouc and other Colloids.

Prof. J. Emerson Reynolds.—Some New Silicon Compounds.

Prof. J. Emerson Reynolds.—Some New Thiocarbamide Compounds.

Prof. J. W. Langley.—Proposed International Standards of Iron and Steel.

Dr. A. Richardson.—Action of Light on Water Colours.

Dr. William Bott and J. B. Miller.—On Pyrocresols.

Profs. Ramsay and Young.—On the Expansion, Vapour Pressures, and Vapour Densities of Water within a Large Range of Temperature.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Solubility of Fatty Acids.—Can any of your readers tell me if the fatty acids of palmitin, stearin, and olein are slightly soluble in hot dilute sulphuric acid of the strength of 1 of acid in 20 of water; if so, to what extent?—D. W. MURCH.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

In the Matter of Letters Patent granted to CHARLES WIGG, of Walmer Buildings, Water Street, Liverpool, in the County of Lancaster, for "Improvements in the manufacture of bicarbonate of soda and in apparatus therefor," dated 29th June, 1887, No. 9227.

NOTICE IS HEREBY GIVEN that the said C. Wigg has applied for leave to amend the Specification numbered as above.

A copy of the Specification as proposed to be amended can be inspected at the Patent Office; and particulars of the proposed amendment were set forth in the Official Journal of the Patent Office issued on the 8th of September, 1888.

Any person intending to oppose the said application must leave notice of objection thereto (on Form G) at the Patent Office, 25, Southampton Buildings, London, W.C., within one Calendar month from the date hereof.

Dated this 8th day of September, 1888.

(Signed)

H. READER LACK, Comptroller-General.

NOTICE.

The STUDENTS' NUMBER of the CHEMICAL NEWS will be published on Friday, September 21st. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the education, who have not yet forwarded the necessary information to our Office for publication in that Number, will confer a favour by sending it with the least possible delay.

Advertisements for this Number should reach the Office not later than Wednesday, the 19th prox.

OWENS COLLEGE, Victoria University, MANCHESTER.

CHEMISTRY COURSE.—Full particulars of this Course, qualifying for the Victoria University DEGREES in CHEMISTRY and the COLLEGE TECHNOLOGICAL CHEMISTRY Certificate, will be forwarded on application.

The Session commences October 2nd.

H. W. HOLDER, M.A., Registrar.

The London Hospital and Medical College, MILE END, E.

The SESSION 1888-89 will commence on Monday, October 1st, 1888. The new buildings which were opened by T.R.H. the Prince and Princess of Wales, on May 21st, 1887, afford more than double the accommodation which was provided formerly.

Four Entrance Scholarships, value £60, £40, £30, and £20, will be offered for competition at the end of September to new students. Fees for lectures and hospital practice, 90 guineas in one payment, or 100 guineas in three instalments. All resident and other hospital appointments are free, and the holders of all the resident appointments are provided with rooms and board entirely free of expense. The resident appointments consist of five house physicians, five house surgeons, one accoucher, and one receiving-room officer; one senior dresser to out patients, dressers and maternity pupils also reside in the Hospital. Special classes for the preliminary scientific and Intermediate M.B. Examinations of the University of London and for the Primary and Pass Examinations for the Fellowship of the Royal College of Surgeons of England are held throughout the year. Special entries may be made for medical and surgical practice. The London Hospital is now in direct communication by rail and tram with all parts of the metropolis, and the Metropolitan, Metropolitan District, East London, and South Eastern Railways have stations within a minute's walk of the Hospital and College.

For prospectus and particulars apply, personally or by letter, to
MUNRO SCOTT, Warden.

WILLIAM FOX, ANALYTICAL CHEMIST, LABORATORY:

4, GREAT TOWER STREET, LONDON. E.C.

Analyses of Oils, Pigments, Varnishes, &c.

Water-Glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester

Silicates of Soda and Potash in the state of Soluble Glass, or in CONCENTRATED SOLUTION of first quality, suited for the Manufacture of Soap and other purposes supplied on best terms by W. GOSSAGE and Sons, Soap Works, Widnes, Lancashire.

London Agents, COSTE and Co., 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

MICA.

F. WIGGINS & SONS, 10, Tower Hill, London, E.
IMPORTERS AND MERCHANTS,
Manufacturers of Mica Goods for Philosophical and ALL purposes.
Contractors to Her Majesty's Government.

Balances.

OTTO WOLTERS.

EMPTY PETROLEUM BARRELS.

RECEIVING WHARVES.

EAST.....BOW—ATLANTIC WHARF
SOUTH.....OLD KENT ROAD, WESTERN WHARF.
RIVERMILLWALL, ST. ANDREWS WHARF.

Empties may also be delivered for our account to

PALMER'S WHARF, BETHNAL GREEN.

THAMES HAVEN PETROLEUM WHARF, THAMES HAVEN.

Or ANY RAILWAY DEPOT WITHIN 4 MILES OF THE ROYAL EXCHANGE, LONDON.

N.B.—All Empties delivered at a Railway Depot as above will be collected at our Expense. No charge to the Sender.

The same price paid for Russian as for American Empties.

OUR PRICE TO DAY is 8s. 6d., DELIVERED AT A RAILWAY DEPOT IN LONDON.

Special Terms offered to Collectors and Costermongers.

Parcels of 15 barrels and over collected at sellers' own premises if within 4 miles of the Royal Exchange, London, and the same price given as would be paid by other receivers for delivery at their wharf.

NOTICE.—In the case of Empties sent for our account to a Railway Depot or to Palmer's or Thames Haven Wharf, please advise us when sending, and mark the barrels with K in yellow paint, so that we can recognise them.

In the case of sellers wishing us to collect from their own premises, we shall be glad of two days' notice.

DEDUCTIONS FOR DAMAGE.—Broken Chimb or Stave 6d., broken Head 6d. to 1s. 6d., according to extent of damage.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1504.

ADDRESS TO STUDENTS.

WE have repeatedly in our "Students' Number" attempted to give some hints to those who are desirous of acquiring a knowledge of chemistry. To what extent our advice has been taken we know not. We have always insisted upon the importance of thoroughness and accuracy, and have advised all who have the necessary opportunities not to rest content with a mere verbal knowledge of the subject, but to qualify themselves as far as possible for original investigation. Perhaps such advice was unpalatable: perhaps it was rejected of compulsion as clashing with the great aim of the English student, to "pass."

Be this as it may, the conviction seems spreading that our method of teaching chemistry,—and by a parity of reasoning the other physical and natural sciences,—is scarcely what might be either desired or expected. With all the increased attention latterly paid to chemistry, with all our schools and classes and laboratories and manuals,—which are indeed legion,—and with all our everlasting examinations we make little head-way. We have not yet recovered our lost supremacy in the chemical arts, and foreigners still occupy among us not merely professorial chairs but the most important posts in our manufacturing establishments.

We have always maintained that examinationism, with its appendage "payment by results,"—so-called—is, if not *the* cause, at least one of the main causes of our unsatisfactory position. We are told, ever and anon, that examinationism is the great foe to originality.

Now it is interesting to note that in the Chemical Section of the British Association a paper has just been read on our method of teaching chemistry, the conclusion being arrived at that it is not satisfactory. We begin too often with abstractions, such as atoms and molecules, and in so doing we reverse the order of nature. Nay, even the elements are conceptions not sufficiently concrete for the earlier lessons of the pupil. Why not begin with some compound, or some naturally occurring and familiar substance of a kind which may interest the learner? As an instance we find mentioned by a contemporary, certain substances in which boys take only too lively an interest; to wit, squibs, crackers, and fire-works in general. Now sulphur is certainly to the chemist very much what iron is to the engineer, the starting-point for his operations. For all that we mistrust the introduction of pyrotechny as the first step in chemistry. Boys already mutilate and damage themselves every autumn to no small extent, and sadly interfere with the peace of mind of their mature relatives. Again, danger to the youthful experimentalist being altogether ignored, we might ask whether the attention of inventors is not already turned to an unprecedented and increasing degree to the concoction of novel explosives, and whether it would be desirable to give any further impulse to this tendency? Surely some other branch of applied chemistry might be found equally instructive and more free from objections. What of colour chemistry? Numbers of boys have a propensity for dyeing, staining, and colouring, or,

as their mothers and sisters call it, messing and smearing. Could not this inclination be usefully directed? All this, however, we must confess is not so much advice to students as suggestion to teachers; and the English teacher and even college professor enjoys little *Lehrfreiheit*. He cannot, like his German colleague, teach chemistry according to the dictates of his own judgment and the results of his own experience. He must conform to some "syllabus" under well-known penalties. Yet we still wonder that our chemical schools are not sufficiently fruitful in discoverers!

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, and all candidates for Matriculation will henceforth be required to comply with the following instructions:—(1) Not less than five weeks before the commencement of the Examination every candidate must apply to the Registrar, by letter, for a Form of Entry, which, together with all particulars respecting the arrangements for the Examination, will be sent to him immediately on receipt of the application. (2). This form, duly filled up, must be returned to the Registrar not less than four weeks before the commencement of the Examination, and with it, in the same cover, must be sent (a) the candidate's certificate of age, and (b) his fee for the Examination. No candidate's name will be placed on the list of candidates unless his form of entry, certificate of age, and fee shall have been received at the University on or before the fourth Monday before the commencement of the Examination. As soon as possible after the closing of the list, and not previously, each candidate's certificate and fee will be acknowledged, his certificate will be returned, and a Number, by which he is to be designated throughout the Examination, will be assigned to him.

The Fee for this examination is £2.

There are two Examinations for Matriculation in each year; one commencing on the second Monday in January, and the other on the third Monday in June. The Examination is conducted by means of Printed Papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the candidates to pass, *viva voce* questions to any candidate in the subjects in which they are appointed to examine.

Candidates are not approved by the Examiners unless they have shown a competent knowledge in each of the following subjects:—Latin. Any one of the following Languages:—Greek, French, German, Sanskrit, or Arabic. The English Language, English History, with the Geography relating thereto. Mathematics. Mechanics. One of the following branches of Experimental Science:—Chemistry, Heat and Light, Magnetism and Electricity.

The Examination in Chemistry is—Chemistry of the Non-metallic Elements; including their compounds—their chief physical and chemical characters—their preparation—and their characteristic tests.

A Pass Certificate, signed by the Registrar, will be delivered to each candidate who applies for it, after the Report of the Examiners has been approved by the Senate.

If in the opinion of the Examiners any candidates in the Honours Division of not more than twenty years of age at the commencement of the Examination possess sufficient merit, the first among such candidates will receive an Exhibition of thirty pounds per annum for the next two years; the second among such candidates will receive an Exhibition of twenty pounds per annum for the next two years; and the third will receive an Exhibition of fifteen pounds per annum for the next two years;

such exhibitions are payable in quarterly instalments, provided that on receiving each instalment the Exhibitor declares his intention of presenting himself either at the two Examinations for B.A., or at the two Examinations for B.Sc., or at the Intermediate Examination in Laws, or at the Preliminary Scientific M.B. Examination, and Intermediate Examination in Medicine, within three academical years from the time of his passing the Matriculation Examination.

Under the same circumstances, the fourth among such Candidates will receive a prize to the value of ten pounds in books, philosophical instruments, or money; and the fifth and sixth will each receive a prize to the value of five pounds in books, philosophical instruments, or money.

Any candidate who may obtain a place in the Honours Division at the Matriculation Examination in January is admissible to the Intermediate Examination either in Arts or in Science in the following July.

INTERMEDIATE EXAMINATION IN SCIENCE.

The Intermediate Examination in Science will be held in July, 1889.

No candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this Examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

Examination for Honours.

Candidates for Honours in Chemistry will be examined in Inorganic Chemistry, treated more fully than in the Pass Examination. In addition, they will be examined practically in Simple Qualitative Analysis. This Examination will consist of six hours' examination by two printed papers and of six hours' practical work.

In the Examination for Honours, the Candidate, not being more than 22 years of age at the commencement of the Pass Examination, who most distinguishes himself will receive an Exhibition of £40 per annum for the next two years.

B.Sc. EXAMINATION.

The B.Sc. Examination will be held in October.

Candidates for this Examination are required to have passed the Intermediate Examination in Science at least one academical year previously.

The Fee for this Examination is £5.

Examination for Honours.

The examination for Honours in Chemistry will take place on Monday and Tuesday in the week following the Examination for Honours in Mathematics; on Monday by printed papers (chiefly on Organic Chemistry), and on Tuesday by practical examination in Qualitative and Quantitative Analysis.

The candidate, being not more than 23 years of age, who most distinguishes himself in Chemistry, will receive £50 per annum for the next two years, with the style of University Scholar.

DOCTOR OF SCIENCE.

The examination for the Degree of Doctor of Science takes place annually within the first twenty-one days of June.

No candidate is admitted to the examination for the Degree of D.Sc. until after the expiration of two Academical Years from the time of his obtaining the Degree of B.Sc. in this University.

The Fee for this Examination is £10.

PRELIMINARY SCIENTIFIC (M.B.) EXAMINATION.*

This Examination takes place twice in each year,—once, for Pass and Honours, commencing on the third

Monday in July; and once for Pass Candidates only, commencing on the third Monday in January.

No candidate shall be admitted to this Examination unless he shall have passed the Matriculation Examination, nor unless he have given notice of his intention to the Registrar at least one calendar month before the commencement of the examination.

The Fee for this examination is Five Pounds.

EXAMINATION IN SUBJECTS RELATING TO PUBLIC HEALTH.

A Special Examination will be held in December in subjects relating to public health.

No candidate is admitted to this Examination unless he has passed the Second Examination for the Degree of Bachelor of Medicine in this University at least one year previously; nor unless he shall have given notice of his intention to the Registrar at least two calendar months before the commencement of the Examination.

The Fee for this Examination is £5.

UNIVERSITY OF OXFORD.

Waynflete Professor of Chemistry.—W. Odling, M.A., F.R.S.

Every Student must reside in one or other of the Colleges or Halls, or in licensed lodgings, for a period of three years, passing at least two examinations in Arts, and one in either Mathematics, Natural Science, Law, Modern History, or Theology, when, if he obtain a first, second, or third class, he can take his B.A. Degree; if he do not gain such honour he has to pass a third examination in *Literis Humanioribus*.

The fee for students working in the Laboratory for three days in the week during the Term is £3; for students working every day, £5.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other colleges, by competitive examination in Natural Science.

More detailed information may be obtained from the University Calendar; from the professors; and from the Sub-Librarian in the Radcliffe Library or the Museum.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A., F.R.S.
Jacksonian Professor of Natural and Experimental Philosophy.—J. Dewar, M.A., F.R.S.

The Student must enter at one of the Colleges, or as a Non-collegiate Student, and keep terms for three years by residence in the University. He must pass the previous examination in Classics and Mathematics, which may be done in the first or second term of residence, or through the Oxford and Cambridge Schools Examination Board, or through the Senior Local Examinations, before commencing residence. He may then proceed to take a Degree in Arts, either continuing mathematical and classical study, and passing the ordinary examinations for B.A., or going out in one of the Honour Triposes.

The scholarships, ranging in value from £20 to £80 a year, are chiefly given for mathematical and classical proficiency. Scholarships are given for Natural Science in Trinity, St. John's, St. Peter's, Clare, Christ's, Sidney, Pembroke, Caius, and Downing Colleges; the examinations being at Easter, and in June and October.

The Chemical Laboratory of the University is open daily for the use of the Students. The Demonstrators attend daily to give instructions.

Non-collegiate Students are allowed to attend certain of the College Lectures and all the Professors' Lectures, and have the same University status and privileges as the other Students. Full particulars may be obtained by forwarding a stamped directed envelope to the Assistant Registrar, Cambridge, or from the *Cambridge University Calendar*.

UNIVERSITY OF DUBLIN.

TRINITY COLLEGE.

Professor of Chemistry.—J. Emerson Reynolds, M.D. F.R.S.

* Candidates who pass in all the subjects of the Preliminary Scientific (M.B.) Examination, and also pass at the same time in the Pure and Mixed Mathematics of the Intermediate Examination in Science, or who have previously passed the Intermediate Examination in Arts, are admissible to the B.Sc. Examination.

Assistant Lecturer.—Augustus E. Dixon, M.D., F.C.S.
Demonstrators.—William Early, F.I.C., and Emil A. Werner.

The general Laboratories now include working accommodation for 120 Students, and the Quantitative and Research Laboratories for about 40 Students. The new Lecture Hall provides full accommodation for 340 Students. Lectures will commence about November 1st.

The Laboratories and the Lectures of the Professor of Chemistry can now be attended by Students who do not desire to reside in the University or proceed to its Degrees.

The full Course of General and Analytical Chemistry occupies three years, but a Student is free in his third year to devote most of his time to a special department of Pure or Technical Chemistry. Students can enter for any portion of the Course. The following Lectures are delivered:—

1. *Inorganic Chemistry and Chemical Philosophy.*—Elementary, first year; advanced, second year.
2. *Organic Chemistry.*—General, second year; advanced, third year.
3. *Metallurgy.*—A Course for Engineering and Technical Students.

The Laboratories are open every day from 10 to 5 o'clock (except Saturdays, when they close at 1 o'clock).

The Summer Course of Practical Chemistry for Medical Students begins during the first week in April and terminates with the first week in July.

KING'S COLLEGE.

(DEPARTMENT OF ENGINEERING AND APPLIED SCIENCE.)

Professor of Chemistry.—J. M. Thomson, F.C.S.

Demonstrator of Practical Chemistry.—G. S. Johnson, F.C.S.

Assistant Demonstrator.—Herbert Jackson, F.C.S.

On Tuesday and Thursday at 10.20 a.m. Students of the First Year are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a View of the Forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-metallic elements and their principal Compounds are described.

The Metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts; and the processes of the different Manufactures and of Domestic Economy are explained and illustrated.

Examinations of the Class, both *visà voce* and by written papers, are held at intervals during the course at the usual Lecture hour.

Second Year.—Students attend in the Laboratory twice a week, on Tuesday and Friday, at 10.20, and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this Department may be admitted to this Class at any period of his study on payment of an extra fee.

Experimental and Analytical Chemistry in the Laboratory.—The object of this Class is to afford to Students who are desirous of acquiring a knowledge of analysis, or of prosecuting original research, an opportunity of doing so under the superintendence of the Professor and Demonstrator; Students may enter, upon payment of extra Fees, at any time except during the vacation, and for a period of one, three, six, or nine months, as may best suit their convenience. The laboratory hours are from ten till four daily, except Saturday, on which day the hours are from ten till one.

In addition to the Laboratory Fee, each Student defrays the expenses of his own Experiments. The amount of this expense, which is comparatively trifling, is entirely under his own control.

Special hours and fees are arranged for the convenience of such Third Year Students as wish to study Analytical Chemistry.

Fees.—Chemistry per term, £3 8s. od.; per ann., £8 8s. od.; Practical Chemistry per term, £4 4s. od.; per ann., £10 10s. od.; Experimental and Analytical Chemistry—One Month (daily attendance), £4 5s. od.; Three Months (daily attendance), £10 10s. od.; Six Months (daily attendance), £18 18s. od.; Nine Months (daily attendance), £26 5s. od. A student taking a month's ticket may attend daily during 1 month, or 3 days a week during 2 months, or 2 days a week during 3 months.

Rules as to Admission of Students.

I. The Academical Year consists of Three terms: Michaelmas Term, from beginning of October to the week before Christmas; Lent Term, from the middle of January to the week before Easter; Easter Term, from Easter to the beginning of July.

II. The days fixed for the Admission of New Students in the Academical Year 1888-89, are Tuesday, October 2, Wednesday, January 16, and Wednesday, May 1.

METALLURGY.

Professor.—A. K. Huntington, F.I.C., F.C.S., &c.

The following subjects are treated of in the Lectures: The Selection and Economic Preparation of Fuel and of Refractory Materials; the methods by which metals are obtained from their ores, and the means by which they are rendered suitable for the various requirements of the Arts.

Particular attention is made to the study of the Nature and Properties of Metals and Alloys available for Constructive Purposes.

In the Metallurgical Laboratory, which is always open during College hours, the relation between the Chemical Composition of Metals and their Mechanical Properties may be studied by the aid of Testing Machinery. The instruction given to each student is regulated by his special requirements.

PHOTOGRAPHY.

Lecturer.—J. M. Thomson, F.R.S.E., F.C.S.

Arrangements are made for a complete Course of Instruction in Photography to the students of the third year. A glass house has been erected, and in connection with it a Laboratory for the preparation of Photographic Chemicals. Students entering to this department will be afforded every facility for practising the Art in all its branches.

In addition to the regular College Course in Photography occasional classes are formed, consisting each of about six gentlemen, who meet twice a week. The fee for private instruction is £5 5s. for ten lessons, or £10 10s. for three courses. There is in every case a charge of £1 each course for chemicals.

EVENING CLASSES.

Classes for Evening Instruction in various subjects are held during the months from October to March, inclusive, and during the months of April, May, and June.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Professor.—William Ramsay, Ph.D.

Assistant Professor.—R. T. Plimpton, Ph.D.

Assistants.—S. Rideal, D.Sc., F.C.S., N. Collie, Ph.D.

The Session is divided into three Terms, as follows, all the dates being inclusive:—

First Term, from Thursday, October 4th, until Friday, December 21st;

Second Term, from Tuesday, January 8th, 1889, till Saturday, March 23rd;

Third Term, for Lectures, from Monday, March 25th, till Tuesday, June 18th. Class Examinations occupy about ten days, beginning on Wednesday, June 19th.

Students, who having entered in October do not intend to present themselves in all three subjects at the July Preliminary Science Examination, should during the first term confine their attention to Chemistry, and take this subject alone at the January Examination.

Students entering in January should take Physics and Biology at the July Examination, and Chemistry at the succeeding January Examination.

Junior or Matriculation Course.

Tuesday, Thursday, and Saturday, at 10, commencing October 4, 1888, and April 2nd, 1889. Fee:—£4 4s.

These Courses will each consist of about thirty lessons, partly theoretical and partly practical, on the non-metallic elements. Frequent exercises will be given.

Senior Course of Chemistry.

First and Second Terms: Inorganic.—The Class meets four times a week: Mondays, Wednesdays, Fridays, and Saturdays, at 9, for Lectures, Examinations, and Exercises.

Fee:—For the Course, £7 7s.; Perpetual, £9 9s.; for the First or Second Terms, £4 4s.

This Course and the Practical Class cover the subject as prescribed for the Preliminary Scientific (M.B.) and Intermediate Examination in Science of the University of London.

For the Preliminary Scientific Examination Students who take the three subjects for that examination in July attend during the First and Second Terms.

Advanced Course of Chemistry.

Second and Third Terms.—The class meets twice a week, on Tuesdays and Thursdays, at 9. The hour will be altered by special arrangement with the class if necessary.

Fee:—For the Course, £5 5s.; for the Second or Third Terms, £3 3s.

This Course will be found suitable for those about to proceed to graduation as Bachelor of Science in London University, and to those who intend to choose Chemistry as a profession. Such students should also work in the Laboratory during as many hours as they can spare.

Organic Chemistry.

Tuesday, Thursday, and Saturday, at 10, in the Second Term; and Monday, Wednesday, and Friday, at 9, in the Third Term. The hour of meeting will be altered should the class desire it.

This Course of Organic Chemistry is intended for those who in studying the subject have not a Medical Examination chiefly in view. Candidates for Honours at the Int.M.B. are, however, recommended to attend this Course during the Second and Third Terms, instead of the Special Summer Course.

The Course includes the subjects required at the B.Sc. Examination, Pass and Honours; but no previous acquaintance with Organic Chemistry will be expected of those joining the Class.

Fee:—For the Course, £6 6s.; for a Term, £2 12s. 6d.

An Advanced Course for those engaged in prosecuting research in Organic Chemistry will be held three times a week during the Second Term. Fee, £2 12s. 6d.

Practical Class.

First and Second Terms, on Tuesday and Thursday, at 11.

Fee, including cost of materials, £5 5s.; for a Second Course, £3 3s.

The Course includes the Practical Chemistry required at the Preliminary Scientific and Intermediate Science Examinations.

Senior Practical Class.

Saturdays from 10 to 12 during the Third Term, and two other hours to be arranged.

Fee:—(Including cost of materials) £5 5s.; for a Second Course, £3 3s.

Analytical and Practical Chemistry.

The Laboratory is open daily from 9 a.m. to 4 p.m., Saturdays excepted, from October until the middle of July, with a short recess at Christmas and at Easter.

Fees: for the Session, £26 5s.; six months, £18 18s.; three months, £10 10s.; one month, £4 4s.

Three specified days a week:—for the Session, £15 15s.; six months, £11 11s.; three months, £6 6s.; one month,

£2 12s. 6d., exclusive of expense of materials. Students may enter at any period of the Session.

The Laboratory Course includes the Practical Chemistry required at the following Examinations of the University of London:—Prel. Sci. (M.B.), Intermediate M.B., Intermediate Science, B.Sc.

Students who wish to attend the Laboratory and Classes of Technical Chemistry may acquire here the requisite preliminary knowledge of Practical Chemistry and Analysis.

When accompanied by, or preceded by, attendance on the Lectures on Chemistry and Organic Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to Manufactures, Metallurgy, Medicine, or Agriculture, &c.

There is also a Chemical Library containing the chief Journals and Standard Works on Chemistry.

A Gold Medal and Certificates of Honour are competed for by Students entered for the Session. The Tuffnell Scholarship (£100 for two years) will also be competed for in the Session 1888-9.

Chemical Technology.

Professor.—Charles Graham, D.Sc., F.I.C.

Assistants.—C. J. Wilson, F.C.S., and A. C. Chapman, F.C.S.

The Course of instruction in this Department is designed to afford to Students who propose to devote themselves to industrial pursuits in which Chemistry plays an important part, or to prepare themselves for the profession of Consulting Chemist, the instruction essential for their success in their future line of work. It will also be found of great value in two of the branches (Organic and Inorganic Chemistry) in which the Degree of Doctor of Science can be taken at the University of London.

In the Session 1888-89, it is proposed to treat of the following subjects:—

Heating and Lighting.

Metallurgy.

The Chemistry of the Alkali trade.

Agricultural Chemistry.

Fees—for each Course, £2 2s.; for two Courses, £3 3s. for the four Courses, £5 5s.

Courses of Lectures will also be delivered on the Chemistry of Brewing (fee, £3 3s.), and on Chemistry in its relation to Engineering and Architecture (fee £2 2s.).

Laboratory of Chemical Technology.

The instruction in the Laboratory of Chemical Technology will consist of the examination and valuation of raw materials used, and of the final products obtained in various manufacturing industries, and of experimental examination of the processes employed in the arts and manufactures.

The Laboratories are open daily from 9 a.m. to 4 p.m., from the 8th of October until the middle of July, with a short recess at Christmas and at Easter.

Fees—for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas exclusive of the expense of materials.

Residence for Students.

Students can obtain residence at University Hall, Gordon Square. Particulars can be obtained at the office of the College.

NORMAL SCHOOL OF SCIENCE AND
ROYAL SCHOOL OF MINES.

Professor.—T. E. Thorpe, Ph.D., B.Sc., F.R.S.

Assistant Professor.—F. R. Japp, M.A., Ph.D., F.R.S.

Demonstrators.—P. F. Frankland, Ph.D., B.Sc., and H. Chapman Jones.

Assistants.—G. S. Newth, A. E. Tutton, and F. Guthrie.

The Normal School of Science at South Kensington is intended, primarily, for the instruction of teachers, and of students of the industrial classes selected by competition in the examinations of the Science and Art Department. The Royal School of Mines is affiliated to the Normal

School. Students entering for the Associateship of the School of Mines obtain their general scientific training in the Normal School. The instruction in the Normal School is arranged in such a manner as to give the Students a thorough training in the general principles of Science, followed by advanced instruction in one or more special branches of Science. The Associateship is granted in certain divisions or lines of study. Students who go through any one of the prescribed courses of instruction and pass the necessary Examinations receive a Certificate of Associateship of the Normal School, or of the Royal School of Mines. But students who are not candidates for the Associateship are permitted to take up the course of instruction in one or more special branches of science, and on passing the examination receive a Certificate to that effect. The Associateship of the Normal School of Science is given in one or more of the following divisions:—Mechanics, Physics, Chemistry, Biology, Geology, and Agriculture, and the Associateship of the Royal School of Mines in Metallurgy and Mining.

The course of instruction, which lasts for three years, is the same for all the divisions during the first year, after which it is specialised in accordance with the Scheme detailed in the Prospectus of the School.

The Session is divided into two Terms. The first Term begins about the 4th of October and ends about the middle of February. The second Term begins in the middle of February and ends about the middle of June.

Examinations are held at the end of each course of instruction and at such other periods as may be found necessary. On the results of these examinations the successful candidates are arranged in two classes, first and second. There are also "Honours" examinations for the subjects of the third year, the successful candidate being placed in order of merit. A student obtains the Associateship who passes in all the subjects of the first two years and of the special division he selects for his Associateship. A student who goes through the prescribed course of instruction in any subject and passes the final examination in it receives a certificate to that effect.

Students who do not wish to attend the lectures are admitted for short periods to the laboratories, at the discretion of the Professors. The fees for the laboratories are £4 per month.

Students not entering for the Associateship are admitted to any particular course of study, so far as there is room, on payment of the fees shown in the following table, which must be paid to the Registrar of the School before the commencement of each course.

	Lectures.	Laboratory.
Chemistry	£ 3	13
Physics	5	12
Biology with Botany .. .	5	12
Geology with Mineralogy ..	4	8
Mechanics	4	6
Metallurgy	2	13
Mining	4	
Agriculture	4	10
Astronomical Physics .. .	2	

Mathematics and Mechanical Drawing £3 per term. Geometrical Drawing, £3 per session. Freehand Drawing, £1 per term.

Thus the fees for the first two years amount to about £75, and for the remainder of the course for the Associateship they vary from £30 to about £40.

Both the private and the State-aided students are required to furnish themselves with certain instruments and apparatus before the commencement of the courses. These are enumerated in the syllabuses of the several subjects.

Officers of the Army, Navy, and Civil Service, recommended by their respective Departments, are admitted to the Lectures and Laboratories at half the foregoing charges.

Associates of the Normal School of Science or of the Royal School of Mines have the privilege of free admission to the Library and to all the courses of lectures.

Science teachers actually engaged in teaching who are registered by the Science and Art Department as qualified to earn payments for teaching Science may attend any course of lectures on the payment of £1.

Several valuable Exhibitions, Scholarships, and Prizes are attached to the studentship.

Summer Courses for Teachers.—Short courses of instruction are given annually, about July, in different branches of science for the benefit of teachers of science schools in the country. The courses last three weeks. About 200 teachers are admitted to them, and they receive 3rd class railway fare to and from South Kensington, and a bonus towards their incidental expenses of £3 each. (See Science Directory.)

Working Men's Lectures.—Three courses of evening lectures for working men will be given during the session in Geology, Mechanics, and Metallurgy. The admission to each course of six lectures will be 6d. The number of tickets is limited by the size of the lecture theatre.

UNIVERSITY COLLEGE OF WALES, ABERYSTWYTH.

Professor.—H. Ll. Snape, D.Sc., F.C.S.

The College is open to male and female students not under the age of 15 years. The Session opened on Tuesday, September 8.

Lecture Courses.—Matriculation Course, during Lent and Easter Terms. Intermediate Science Pass Course, during Lent and Easter Terms. Intermediate Science Honours Course, during Lent and Easter Terms. B.Sc. Course, throughout the Session.

Laboratory Courses.—Intermediate Science Pass Course, Intermediate Science Honours Course, and B.Sc. Course.

The Fee for the whole Session, paid in advance, is £10; if paid by single Terms, for the first Term of attendance in each Session £4; for the second Term, £3 10s.; for the third Term £3. Any person wishing to attend single classes may do so on payment of the sum of £1 per Term for each class.

Practical Chemistry.—The Laboratory is open to Students daily during the Session from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except Saturdays.

Special courses will be arranged for those Students who intend following Medicine or Pharmacy, and every facility will be given to those desirous of studying more especially some one particular branch of Applied Chemistry.

Several valuable Scholarships and Exhibitions are attached to the Studentship.

UNIVERSITY COLLEGE OF SOUTH WALES AND MONMOUTHSHIRE.

Professor.—C. M. Thompson, M.A., D.Sc., F.C.S.

Demonstrator.—J. Tudor Cundall.

The Session commences October 1st, and terminates in June, and is divided into three terms.

The Junior Course (delivered during the Michaelmas term only) consists of about 55 lectures, and will cover the subjects prescribed for the London University Matriculation examination. Fee, £2 2s.

The Intermediate Course consists of 90 lectures in continuation of the Junior Series, and, together with laboratory practice, will cover the subjects required for the Intermediate Examination in Science and the Prel. Sci. (M.B.) Examination of the University of London. Fee £3 3s.

The Senior Course includes some 90 lectures devoted to Organic Chemistry; Fee, £3 3s.

A course of 30 lectures on Qualitative and Quantitative Analysis and Chemical Calculations. £1 1s.

The Laboratory Course may be modified to meet the requirements of individual students wishing to obtain a special knowledge in some branch of manufacturing or industrial chemistry. Hours, 9 to 1 and 2 to 4.30; Satur-

day, 9 to 1. Fees—Six hours per week, £3 3s. per session; twelve hours, £2 2s. per term; eighteen hours, £3 3s. per term; twenty-four hours, £4 4s. per term.

Professors Thompson and Parker are recognised by the Universities of Edinburgh and Glasgow as teachers in Chemistry and Natural History respectively, so that registered Medical Students can spend one year of their course at the University College, Cardiff. The College is also recognised as an institution at which two years of the course for the degree of Bachelor of Science of the University of Edinburgh may be spent.

Evening Lectures.—A course of Lectures will be given on Elementary Chemistry. The Laboratory will be open on Monday evenings during the Michaelmas and Lent terms.

At the entrance examination in September, and the annual examination in June, several scholarships, &c., are awarded.

A Hall of Residence for Female Students is attached to the University, and new Chemical, Physical, &c., Laboratories were opened by Sir William Grove in October last.

UNIVERSITY COLLEGE, BRISTOL.

Professor of Chemistry.—Sydney Young, D.Sc.

Lecturer.—Arthur Richardson, Ph.D.

The session 1888-89 will begin on October 10. Lectures and classes are held every day and evening throughout the Session. In the Chemical Department lectures and classes are given in all branches of theoretical chemistry, and instruction in practical chemistry is given daily in the chemical laboratory. Excursions to some of the mines, manufactories, and chemical works of the neighbourhood are occasionally made. The department of experimental physics includes various courses of lectures arranged progressively, and practical instruction is given in the physical and electrical laboratory. The Department of Engineering and the Constructive Professions is designed to afford a thorough scientific education to students intending to become engineers, or to enter any of the allied professions, and to supplement the ordinary professional training by systematic technical teaching. This department includes courses specially arranged for students intending to become civil, mechanical, electrical, or mining engineers, surveyors, or architects. Those who attend the mechanical engineering course enter engineering works during the six summer months, and, in accordance with this scheme, various manufacturing engineers in the neighbourhood have consented to receive students of the College into their offices and workshops as articled pupils. Medical education is provided by the Bristol Medical School, which is affiliated to the College. Several Scholarships are tenable at the College.

DAY LECTURES.

Inorganic Chemistry.

The Course treats of the principles of Chemistry, and of the Chemistry of the Non-Metals and Metals.

Lectures will be given daily at 9 and 10 o'clock.

Organic Chemistry.

This Course will relate to the more important groups of the Compounds of Carbon.

Lectures will be given during the Second Term on Tuesdays and Thursdays at 10 o'clock; during the Third Term on Tuesdays, Thursdays, and Saturdays at 10 o'clock.

Fee, £3 3s.

Practical Chemistry.—Laboratory Instruction.

The Laboratory will be open daily from 10 a.m. to 5 p.m., except on Saturdays, when it will close at 1 p.m. Instruction will be given in the Laboratory in all branches of Practical Chemistry, including Qualitative and Quantitative Inorganic and Organic Analysis, the preparation of Chemical Products, and Inorganic and Organic Research. Special facilities will be afforded to those who desire to study Practical Chemistry as applied to the different processes employed in the Arts and Manufactures, and to Scouring, Bleaching, and Dyeing. The Laboratory is

under the immediate supervision of the Professor and the Lecturer.

Fees in Guineas—

	6 Days a Week.	5 Days a Week.	4 Days a Week.	3 Days a Week.	2 Days a Week.
Per Session ..	17	15	13	10	7½
„ Two Terms ..	13	11	9	7½	5½
„ One Term ..	7	6	5	4	3
„ Month ..	3	3	2	2	1½

Students may arrange to divide their days of laboratory work into half-days.

Photographic Chemistry.

A Course of Lectures will be given by Mr. A. Richardson, Ph.D., on Mondays at 10, which will cover the subject as prescribed for the Technological Examination of the City and Guilds of London Institute; fee, £1 1s. for each term. The Photographic Laboratory is open from 10 to 5 every Wednesday; fee, £3 3s. for each term. A Course of Evening Lectures on the same subject will also be given on Fridays at 7.

EVENING LECTURES.

This course will consist of Two Lectures a week during the First and Second Terms; they will be devoted to the consideration of the general Principles of Chemistry and Chemical Physics and the Chemistry of Non-Metallic Elements. Special attention will be paid throughout to those products which have a practical application in the Arts and Manufactures.

Fee, 15s. for Two Terms; 10s. for One Term.

Special Courses of Lectures will be given during the First Term on the Chemistry of Potting, Tuesdays, at 8; and during the Second Term on Elementary Chemistry as Applied to Brewing, Mondays, at 8.

Chemical Scholarship.—Among others, a Chemical Scholarship of £25 is offered for competition.

With the approval of the Council of the Institute of Chemistry students desiring to qualify as Associates may pass through the requisite amount of study at this College, which has also been approved as a centre for the Practical Examination of the Institute.

MASON SCIENCE COLLEGE, BIRMINGHAM.

Professor.—W. A. Tilden, D.Sc. Lond., F.R.S.

Assistant Lecturer.—W. W. J. Nicol, M.A., D.Sc., Edin.

Demonstrator.—Thomas Turner, F.C.S.

The Session will be opened on Monday, October 1st, 1888.

Elementary Course.

Forty Lectures adapted to the requirements of beginners will be given in the Winter and Spring Terms. A Second Course of Twenty Lectures, having reference only to the subjects included in the syllabus of the Matriculation Examination of the University of London, will be given in the Summer Term. Lecture days—Wednesdays and Fridays at 11.30, Thursdays at 3.30.

Persons entirely unacquainted with Chemistry are recommended to attend the first of these Courses before entering for the General Course, which commences in October. Candidates for the Matriculation Examination of the University of London are advised to attend both these Courses.

General Course.

The General Course of Lectures on Chemistry will be found useful by Students who are afterwards to become Engineers, Architects, Builders, Brewers, or Manufacturers (such as Metallurgists, Alkali, Soap, Manure, Glass, or Cement Makers, Bleachers and Dyers, &c.)

Students preparing for the Intermediate Examination in Science and Preliminary Scientific (M.B.) Examination of the University of London should attend the Lectures on *Inorganic Chemistry* (Winter and Spring Terms).

Candidates for B.Sc. and Intermediate Examinations

in Medicine will in general require only that part of the course (Summer Term) which relates to *Organic Chemistry*.

The full course, extending over three terms, will also satisfy the requirements of Students preparing for the Associateship of the Institute of Chemistry, so far as attendance at lectures on General and Theoretical Chemistry is concerned.

1. From October to March (Winter and Spring Terms). About one hundred lectures on *Inorganic Chemistry and Chemical Philosophy* will be given on Mondays, Tuesdays, Wednesdays, Thursdays, and Fridays, at 9.30 a.m. Fee, £5 5s. for the course.

2. April to June (Summer Term). About forty lectures will be given on *Organic Chemistry*, or the chemistry of the most important series of carbon compounds. This course will include all the subjects required for the Intermediate Examination in Medicine of the University of London. Lecture Days—Monday, Tuesday, Wednesday, Thursday, and Friday at 9.30 a.m. Fee, £2 2s.

In all these courses the instruction will often take the form of class teaching, and exercises will be set which students will be expected to work at home.

An Advanced Course for the study of Theoretical Chemistry and those parts of the subject which are required for the degree of B.Sc. in the University of London will meet once a week. Fee for the session £3 3s.

Laboratory Practice.

The College Laboratory will be open daily from 9.30 to 5, except on Saturdays, when it will be closed at 1 p.m.

Candidates for Intermediate Examination in Science, Preliminary Scientific (M.B.), B.Sc., and Intermediate Examination in Medicine of the University of London, may obtain in the Laboratory of the College the instruction necessary. The three months Course of Practical Chemistry for the B.Sc., Edinburgh, in the department of Public Health, may be taken in the Mason College Laboratory.

The Ordinary Course for Medical Students is given on Mondays, Tuesdays, and Thursdays from 2.30 to 4.30 p.m. throughout the Summer Term.

Fees:—

	All day.	Three hours per day.
One Term	7 guineas	4½ guineas.
Two Terms	13 „	8½ „
Three Terms	18 „	12 „

A Course of short demonstrations and exercises will be given by the Professor or one of his Assistants once a week. All first-year Students will be required to attend, unless exempted for special reasons by the Professor. No Fee.

Metallurgy.—Three Courses of Ten Lectures will be given on the Principles and Practice of Metallurgy. Fee, ros. 6d. for each course.

Arrangements have been made in the Chemical Laboratory for giving instruction in Practical Metallurgy.

Evening Classes.

Several Courses of Evening Lectures are arranged during the Winter and Spring Terms of each session. The subjects are treated in a less technical manner and the fees are nominal.

Excursions.

During previous Sessions permission has been obtained to visit some of the great factories in or near Birmingham, in which chemical and metallurgical industries are carried on. Students have thus had most valuable opportunities of gaining a practical acquaintance with some branches of Applied Science. The privilege thus courteously granted by several manufacturers will, it is hoped, be enjoyed in every future Session. The excursions will be conducted by the Professor.

BRADFORD TECHNICAL COLLEGE.

CHEMISTRY AND DYEING DEPARTMENT.

Professor.—Edmund Knecht, Ph.D., F.I.C.

Demonstrator.—Charles H. Jessop.

Lecturer on Technical Analysis.—C. Rawson, F.I.C. F.C.S.

Lecturer on Botany and Materia Medica.—William West, F.L.S.

The school year is divided into three terms. The Session began on September 17th and terminates on July 7th. The course of instruction extends over two years, and embraces Lecture Courses on Inorganic and Organic Chemistry, the technology of the textile fibres, mordants, natural and artificial colouring matters, technical analysis, and laboratory practice in analytical chemistry, chemical preparations, and dyeing. Inclusive fee, £4 4s. per term.

During the first and second terms Evening Classes are held for the benefit of persons engaged during the day and for pharmaceutical students.

ROYAL AGRICULTURAL COLLEGE, CIRENCESTER.

CHEMICAL DEPARTMENT.

Professor.—Prof. E. Kinch, F.C.S., F.I.C.

Assistants.—A. G. Bloxam, F.C.S., and W. James.

Systematic courses of Lectures are given on the various branches of Chemistry in its relation to Agriculture, illustrated by experiments, and by the collections in the College Museum. They comprise the laws of Chemical Combination and the general Chemistry of mineral bodies, and of the more frequently occurring bodies of organic origin, with the relationships of their leading groups; and, finally, the applications to practical operations of the Chemistry of the atmosphere, of soils and manures, of vegetation and stock feeding, and of the processes and products of the dairy.

In the Laboratory practical instruction is given in the construction and use of apparatus and in Chemical manipulation and analysis, both qualitative and quantitative. After studying the simple operations and the properties of the commonly occurring substances, the Students are taught to analyse a series of compounds, and apply the knowledge thus obtained to the analysis of manures, soils, waters, feeding stuffs, dairy products, and other substances met with in the ordinary course of Agricultural practice. Chemico-agricultural researches are undertaken by the senior Students under the direction of the Professor and his Assistants.

VICTORIA UNIVERSITY.

THE YORKSHIRE COLLEGE, LEEDS.

Professor of Chemistry.—Arthur Smithells, B.Sc. Lond., F.C.S.

Assistant Lecturers.—C. H. Bothamley, F.C.S., and Herbert Ingle.

The Session begins October 1, 1888.

Lecture Courses.

1. General Course of Chemistry.—Monday, Wednesday, and Friday, at 11.30 a.m., from October to the end of the second term. Fee for the Course, £3 13s. 6d.

2. Inorganic Chemistry.—First years' Honours Course, Non-metals, Monday, Wednesday, and Friday, at 9.30 a.m.. Fee, £3 13s. 6d.

3. Inorganic Chemistry.—Second years' Honours Course, Metals. Three hours weekly. Fee, £3 13s. 6d.

4. Organic Chemistry.—Tuesday and Thursday at 12.30 p.m. Fee £2 12s. 6d.

5. Theoretical Chemistry.—Advanced Course. Fee, £1 11s. 6d.

6. Chemistry as Applied to Coal Mining.—Tuesday during the First Term, at 4 p.m.

7. Photographic Manipulation.—A Course of Ten Lessons will be given on Fridays, from 2 to 5, during the

Third Term, with special reference to dry plate processes and silver and platinum printing. Fee, £1.

Laboratory Courses.

The College Laboratory will be open daily from 9 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it will close at 1 p.m.

Fees for the Session—Students working six days per week, £18 18s.; five, £16 16s.; four, £14 14s.; three, £12 12s.

Class in *Practical Chemistry*, Saturday mornings, from 9.30 to 12.30. Fee £1 11s. 6d.

Practical Chemistry for Medical Students.—On Tuesday and Thursday, from 10 to 12 a.m., from May to July.

Evening Classes.

A Course of twenty Lectures by Mr. C. H. Bothamley, on the Elements of Inorganic Chemistry (the Non-Metals) will begin during the first and second Terms, on Wednesdays, at 7.30 p.m., beginning October 10. Fee, ros. 6d.

Dyeing Department.

Professor.—J. J. Hummel, F.C.S.

This Course extends over a period of three years, and is intended for those who wish to obtain a full scientific and practical education in the art of dyeing. It is suitable for those who purpose in the future to take any part in the direction of the operations of dyeing or printing of textile fabrics, e.g., the sons of manufacturers, calico printers, managers, master dyers, &c.

Several valuable Scholarships are at the disposal of the College, viz., the Cavendish, Salt, Akroyd, Brown, Emsley, Craven, and Clothworkers' Scholarships, and the Leighton Trustees' Exhibition.

UNIVERSITY COLLEGE, LIVERPOOL.

Professor.—J. Campbell Brown, D.Sc.

Demonstrators.—C. A. Kohn, B.Sc., Ph.D., and S. G. Rawson, B.Sc.

Assistants.—H. H. Froyssell and A. C. Wilson.

The Session commences October 1st.

The Classes are arranged to suit the requirements of candidates for the Ordinary B.Sc. Degree, or for Chemistry Honours in Victoria University; for Degrees in Medicine of Victoria, London, and Edinburgh; for a special Technological Certificate of University College; and for those studying Chemistry as a preparation for professional, technical, or commercial life. The Classes qualify for the Fellowship of the Institute of Chemistry of Great Britain and Ireland, and other Examination Boards.

Lecture Courses (Elementary).

General Course on the principal non-metallic elements and the most important metals, the principles of Chemical Philosophy, and an introductory sketch of Organic Chemistry.

Course A.—Non-metals.

Course B.—Chemistry of the Metals.

Course D.—Organic Chemistry.

Course E.—I. History of Chemistry and Development of Modern Chemical Philosophy. II. Chemical Physics.

Course F.—Technological Chemistry: Lectures on Technology are given in connection with Laboratory work at hours to be arranged. The subjects are varied in different years. (1) Alkali and Allied Manufactures. (2) Copper. Iron. (3) Distillation of Coal, and Tar Industries. (4) Fuel. (5) Chemistry Applied to Sanitation. (6) Technical Gas Analysis. (7) Spectroscopy.

Practical Classes.

(1) Junior. (2) Intermediate. Saturday, 9.30 a.m. to 12.0. Qualitative Analysis of Inorganic Substances and of some of the more common Organic Substances. (3) Special: For the Conjoint Board of Colleges of Physicians and Surgeons. (4) Senior: Practical Organic (Advanced Medical Class). (5) Practical Exercises on

Technology, Pharmaceutical Chemistry, Sanitary subjects, Adulterations of Drugs and of Food, Examination of Water and Air, of Animal Secretions, Urinary Deposits, Calculi, and Poisons. (6) Quantitative Class. Course arranged to suit the requirements of the London University B.Sc. Examinations, Pass and Honours, and for Intermediate M.B. Honours.

Chemical Laboratory.

The Chemical Laboratories provide accommodation for every kind of chemical work.

TABLE OF FEES.

Per Week.	One Month.	One Term, Three Months.	Two Terms, Six Months.	Three Terms, One Session.
One day ..	—	£4	£6	£8
Two days ..	—	5	8	10
Three days ..	£4	7	10	12
Four days ..	5	8	12	15
Five days ..	—	9	14	18

Students desirous of gaining a thorough theoretical and practical acquaintance with Technical Chemistry, or who intend to adopt Chemical work as a profession, must devote three or four years to special study.

Technological Curriculum.

First Year.—Chemistry, either the Elementary Course or Course A, according to the previous knowledge of the Student. Practical Classes 1 and 2. Mathematics and Mechanics. Engineering Drawing and Design, or this may be taken in following year. French or German. Physics.

Second Year.—Chemistry—Courses A and B; Chemical Laboratory two or three days per week, and the Practical Organic Class during the Summer Term; Technological Chemistry, one Term, Course F.

Third Year.—Chemistry, Lecture Course on Organic Chemistry, D. Lecture Course, E, and Chemical Physics. Technological Chemistry, Course F. Chemical Laboratory, four or five days per week. Engineering—Strength of Materials. The Final Examination for the degree of B.Sc. may be taken if the Student is sufficiently diligent. By spending four years instead of three years, namely, three years after passing the Preliminary Examination, an able Student may take the B.Sc. degree in the Honours School of Chemistry. Students may finally choose a special subject either of research or of applied Chemistry.

Evening Classes.

Lectures will be given on Organic Chemistry, the Manufacture of Alkali and Kindred Industries, and on Thermo-Chemistry.

The Sheridan Muspratt Chemical Scholarship of £50 per annum, tenable for two years, will be awarded in December on an Examination in subjects which are included in the first two years of the above curriculum. Other Scholarships, Entrance Scholarships, and Free Studentships are also available to Students.

The Laboratory is opened for Students from 10 a.m. to 5 p.m. daily, on Saturdays from 10 to 1 only.

The Prospectus containing full particulars may be obtained from Adam Holden, 48, Church St., Liverpool, price 6d.; or from the Registrar, University College, Liverpool.

LIVERPOOL COLLEGE OF CHEMISTRY.

Principal.—George Tate, Ph.D., F.G.S., F.C.S.

The Laboratories are open daily from 10 to 5, excepting Saturdays, when they close at 1 p.m. The course of instruction is adapted to the requirements of students of Chemistry as a science, and in its applications to chemical and metallurgical industries. The fee for a three years' course of study is eighty-five guineas, or per session of three months ten guineas.

Prospectuses, containing full particulars of the day and evening classes, may be had on application at the College.

DURHAM COLLEGE OF SCIENCE,
NEWCASTLE-ON-TYNE.

Professor of Chemistry.—P. Phillips Bedson, D.Sc., F.C.S.

Demonstrator—Saville Shaw.

The Session will commence on October 8th, 1888.

Junior Division: First Year Course.—This Course of Lectures will extend over the three terms of the Session, and is intended to serve as an introduction to the Science. The Lectures will be of an elementary character, and whilst framed to meet the requirements of First Year Students will also be serviceable to such as intend pursuing Chemistry in its various applications in the arts and manufactures, as, for instance, Brewing, Metallurgy, the Manufacture of Soda, Soap, Glass, &c. The subjects treated will include an exposition of the Principles of Chemistry, and a description of the preparation and properties of the chief Elementary Substances, both metallic and non-metallic, and their more important native and artificial compounds. The class will meet on Mondays, Wednesdays, and Fridays, at 11 a.m., and will commence on Wednesday, October 17th.

Senior Division: Second Year Course.—A Course of about ninety Lectures will be given throughout the Session, the subject of which will be Organic Chemistry, or the Chemistry of the Carbon Compounds. This class will meet on Tuesdays and Thursdays, at 11, and Fridays, at 3 p.m., and will commence on Tuesday, October 16th.

Fee, for either Course, five guineas for the Session.

An Advanced Class will be formed for the study of Theoretical Chemistry. Fee, £2 2s.

A Lecture Course in Analytical Chemistry will be given on Mondays, at 3 p.m., commencing October 22nd. Fee, £1 1s.

Practical Chemistry.—The Laboratory is open from 10 a.m. to 1 p.m., and from 2 to 5 p.m., except on Saturdays, when it closes at 1 p.m. *Laboratory Fees.*—Students working six days per week, £5 5s. per term; alternate days, £3 3s.; one day per week, £1 1s.

Courses of Study.—Students will be divided into two classes:—(1) Regular, or Matriculated Students; and (2) Non-Matriculated Students. Regular Students will be required to follow such a course of study in the subjects professed in the College as will enable them to pass the Examinations for the title of Associate in Physical Science. Non-Matriculated Students will attend such classes as they may select. Every candidate for admission as a matriculated student must pass an examination on entrance, in reading, writing from dictation, English or Latin Grammar, arithmetic (including decimals), and geography. Registered students in medicine are exempted from this examination, or students who produce a certificate of having passed either of the two following examinations:—

1. Durham Examination for certificate of proficiency in General Education, held in March and September.

2. Durham Examination for Students in Arts in their first year, or any examination of a similar nature that may be accepted by the Council.

Associateship in Physical Science.—Every candidate for the Associateship in Physical Science will be required to satisfy the examiners in three, at least, of the four subjects,—Mathematics, Physics, Chemistry, and Geology,—in an examination, to be held at the beginning of his second year.

Exhibitions.—Three Exhibitions of the value of £25, £15, and £10 respectively will be awarded in October next to Candidates desirous of attending the first year course of study in the College.

Evening Lectures.—Courses of Evening Lectures will be given, with a Practical Class for Laboratory instruction. The examination will be held at the College, and will commence on Monday, October 8th.

Two Exhibitions of £15 each will be awarded at the next examination of "Persons not members of the University," which will be held at Durham in March next.

Several other valuable Scholarships are available for students.

OWENS COLLEGE,
VICTORIA UNIVERSITY, MANCHESTER.

Professor and Director of the Chemical Laboratory.—Harold B. Dixon, M.A., F.R.S.

Professor of Organic Chemistry.—C. Schorlemmer, F.R.S.

Lecturer on Technological Chemistry.—Watson Smith, F.C.S., F.I.C.

Demonstrators and Assistant Lecturers.—Julius B. Cohen, Ph.D., and George H. Bailey, D.Sc.

The Session begins on October 2, 1888, and ends on June 22, 1889.

The instruction is given by means of Experimental Lectures and Tutorial Classes. The Chemical Classes form part of the Courses for Chemistry in the University.

General Chemistry.

General Chemistry Course.—Tuesdays, Thursdays, and Saturdays, at 9.30, during the two Winter Terms.

Introduction to Organic Chemistry.—Mondays and Fridays, at 10.30, during Lent Term.

These courses are intended for Medical Students and others beginning the study of chemistry.

First Year Honour Course.—Mondays, Wednesdays, and Fridays, 3.30 p.m., during the two Winter Terms. The Non-Metals.

Second Year Honour Course.—Mondays, Wednesdays, Fridays, 9.30, during the two Winter Terms. The Metals.

Third Year Honour Course.—Tuesdays, 11.30. Chemical Physics.

Organic Chemistry (Honours).—Tuesdays, Thursdays, Saturdays, 9.30, during the Session.

History of Chemistry and Chemical Philosophy.—Thursdays, 10.30, during the Session.

Technological Chemistry.

Persons desiring to attend this course will be required to enter the College under the ordinary conditions of studentship.

The object of this course is to offer to students intending to devote themselves more especially to Applied Chemistry as complete a training as the College can provide in those branches of instruction which form the scientific foundation of the subject.

The complete course of instruction extends over four years, and embraces the following subjects:—

First Year.—Chemistry Lectures, General Course. Preparatory:—Chemical Laboratory, two days per week. Pure Mathematics. Elementary Mechanics. Geology. French or German. Geometrical Drawing Lectures (evening class). Mechanical Drawing, Practical (evening class).

Second Year.—Chemistry Lectures, First year Honour classes. Chemical Laboratory, three days per week. Technological Chemistry Lectures. Elementary Physics or Mineralogy Lectures and Practical Courses. German or French. Geometrical Drawing Lectures (evening class). Mechanical Drawing, Practical (evening class).

Third Year.—Chemistry Lectures, Second year Honour. Organic Chemistry Lectures. Chemical Philosophy. Chemical Laboratory, three days per week. Technological Chemistry Lectures (second course). Physical Laboratory, 1 day per week, or Advanced Mineralogy Lectures and Practical Course. Mechanical Drawing, Practical (evening class).

Fourth Year.—Organic Chemistry Lectures. Technological Chemistry Lectures (third year's course). Chemical Laboratory, 4 days per week. Mechanical Drawing, Practical (evening class).

Fees.—Every student is required to pay on admission an entrance fee of £1 1s. and a library fee of 5s., and the fees for the classes for which he enters. As alternative courses are in some instances open to a student offering himself for the Victoria University Examinations, it is not practicable to give tabular statements of the fees

for every combination of classes. Special prospectuses may be obtained at the office of the College.

Certificates will be granted to students on the successful completion of this course. Attendance on the full course of four years is expected of candidates for the Certificate, but students may obtain exemption (on cause shown) from the first or the first and second year's courses. Students so excused will nevertheless be required to undergo examination in all the subjects specified. The Certificate will state in which subjects the candidate has gained Honours, and in which he has merely satisfied the Examiners.

An ordinary degree of B.Sc. in Chemistry may be taken at the College in either two or three years, according as to whether the student passes the Preliminary Examination on joining the College or whether he takes a year to prepare for that examination. The Degree of B.Sc. with Honours in Chemistry can be taken in three years, and the College Certificate in Technological Chemistry may be taken in the same time.

A number of important Exhibitions, &c. are available to students.

UNIVERSITY COLLEGE, NOTTINGHAM.

DEPARTMENT OF CHEMISTRY.

Professor of Chemistry—Frank Clowes, D.Sc. Lond., F.I.C., F.C.S.

Demonstrators.—J. B. Coleman, F.I.C., F.C.S., and R. L. Whiteley, F.I.C., F.C.S.

Lecturers.—J. B. Coleman, F.I.C., F.C.S., R. L. Whiteley, F.I.C., F.C.S., C. Haydon White, M.R.C.S., J. W. Carr, B.A., and F. R. Sargeant.

The Classes of the College are open to students of both sexes above sixteen years of age.

The dates of commencement and end of Terms in the Session 1888-9 will be as follows:—First Term, October 8th to December 22nd; Second Term, January 21st to April 6th; Third Term, April 24th to July 8th.

Lecture Courses.—The Chemistry Day Lectures extend over three years. In the first year a student enters for the course on Non-Metals for the first two terms and for Elementary Organic Chemistry in the third term. In his second year he takes the course on Metals for the first two terms, and Advanced Organic Chemistry in the third term. In his third year he attends a course on Applied Chemistry during the first two terms. Fee for Day Lectures and Classes, 50s. for the session of three terms: Non-Metals or Metals 42s.; Organic Chemistry (one term) 21s.; Applied Chemistry, 30s.

Demonstrations and Lectures on Analytical Chemistry will be given in the day and evening, and should be attended by all first year students.

A Chemical Calculation Class will meet on Friday Evenings at 7. Fee per term, 2s. 6d.

Students may qualify themselves by attendance at these lectures and classes for the Examinations of the Universities of London, Cambridge, or Oxford: they may also obtain instruction in Chemistry for technical or other purposes, and can enter for a full Chemical Engineering Curriculum. Special attention is given to the requirements of candidates for the Associateship of the Institute of Chemistry.

Practical Chemistry.—The chemical laboratory is open every day except Saturday from 10 to 5, on Saturday from 10 to 1, and on Tuesday and Thursday evenings from 7 to 9. Each Student works independently of other Students at a course recommended by the Professor. Instruction is given in general Chemical Manipulation and in Qualitative and Quantitative Analysis; and students are enabled to work out the applications of Chemistry to Pharmacy, Dyeing, Agriculture, Brewing, Iron and Steel, Tanning, and other Manufacturing Processes. Fees.—For one term, £6; for the session, £15; for day students for six hours weekly 40s., and 5s. extra for each additional hour per week. For evening

students, 10s. for one evening per week, and 20s. for two evenings per week, per term.

Courses of Lectures are also given on the Chemistry of Dyeing and Bleaching, the Chemistry of Brewing, the Chemistry of the Coal Mine, and on many applied chemical processes.

A Pharmaceutical curriculum, extending over three Winter Sessions, includes Pharmaceutical Chemistry (lectures and laboratory work), Pharmaceutical Botany (lectures and class work on specimens), Materia Medica (lectures and use of specimens), and Practical Dispensing, taught by demonstrations and practical work in the laboratory.

Government Lectures and Classes.—Evening Lectures and Laboratory instruction will be given by the Demonstrator of Chemistry to Students who intend to present themselves for Examination by the Government Science and Art Department in May next. Inorganic, organic, and practical chemistry, agricultural chemistry, and metallurgy will be taught in the elementary and advanced stages, each of which commences at the beginning of the College Session in October. Fees for each Lecture Course, 2s. 6d.; for each Laboratory Course, 10s. Students joining these classes are expected to become candidates for the Government Examinations in May.

Full information concerning all College Classes is given in the College Prospectus.

FIRTH COLLEGE, SHEFFIELD.

Professor of Chemistry.—W. Carleton Williams, B.Sc., F.C.S.

Demonstrator and Assistant Lecturer.—L. T. O'Shea, B.Sc., F.C.S.

The Session will commence on Tuesday, October 2, 1888.

First Year's Course.—Chemistry of the Non-Metallic Elements. Monday, Wednesday, Friday, from 10 to 11 a.m. Fee, £3 13s. 6d.

Second Year's Course.—Chemistry of Metals. Tuesday and Thursday, from 10 to 11 a.m. £2 12s. 6d.; or for the First and Second Courses, £5 5s.

Third Year's Course.—Organic Chemistry, on Wednesday, from 9 to 10, and Saturday, from 10 to 11. Fee, £2 2s.; Second and Third Courses together, £4 4s.

A Course of Lectures is arranged for Medical Students, with a special class in Qualitative Analysis.

Laboratory.—Working hours to be arranged between Professor and Students.

Sessional Fees for Day Students:—Six hours per week, £5 5s.; Nine, £7; Twelve, £8 8s.; Eighteen, £11 5s.; Twenty-four, £14; Thirty-two, £17.

Day Students may not enter for less than six hours a week. Students joining the Laboratory at Christmas will be charged two-thirds and at Easter one-third of the Fees for the whole Session.

Fees for short periods (working thirty-two hours per week):—For one month, £3 3s.; two months, £5 5s.

An arrangement has been entered into with the Science and Art Department, South Kensington, which will enable Science Teachers to work in the Chemical Laboratory for twelve hours a week on payment of one-quarter of the usual fee, the Department being willing to pay the remainder under certain conditions, of which full information may be obtained on application to the Registrar.

Evening Classes.—Lectures, Monday, 8 to 9. Laboratory instruction, Monday and Wednesday, 6 to 9. Sessional Fee, one evening per week, £1 10s.; two, £3; or Lecture Class and Laboratory, on Monday evening, £1 10s.

UNIVERSITY COLLEGE, DUNDEE.

Professor.—T. Carnelley, D.Sc., F.C.S.

Lecture Assistant.—Andrew Thomson, M.A., D.Sc.

The sixth session of the College will be opened on October 8th, 1888.

The Lectures and Laboratory practice in Chemistry are recognised by the Royal College of Physicians and Royal College of Surgeons, London, and by the Royal College of Surgeons, Edinburgh, and for degrees in Science and Medicine by the University of St. Andrews and Edinburgh.

The courses are suitable for the Degrees of the London University and for the Civil Service appointments, and will also satisfy the requirements of students in Pharmacy, and of students who intend to become candidates for the Associateship of the Institute of Chemistry, so far as attendance at lectures on General and Theoretical Chemistry is concerned.

Lecture Courses.

The object of these courses will be (1) to give systematic instruction in the general principles of the science, and information regarding the elements and their more important compounds; (2) to show how this knowledge may be usefully applied in the Arts and Manufactures.

A course of instruction in Practical Chemistry in the Laboratory is recommended to all who wish to obtain a sound knowledge of the science, and the methods of applying it to useful purposes—the duration of such course depending upon the special wants of the student.—The Professor will be glad to give any information to intending students.

First year's lecture course: Monday, Wednesday, and Friday, from 10 to 11 a.m.; fee, £2 2s.

Second year's lecture course: Tuesday, Thursday, and Saturday, from 9 to 10 a.m.; fee, £2 2s.

A Lecture Course on Analytical Chemistry will be given on Wednesdays, from 9 to 10. Fee, £1 1s.

Courses of lectures will be given on Dyeing, Bleaching, and the Chemistry of the Textile Fibres, with practical instruction in the Laboratory. In connection with this Department there is an extensive Technical Museum, containing a large collection of specimens illustrating many branches of Applied Chemistry, and particularly the local industries.

Practical Chemistry (Laboratory).

The aim of the Laboratory Courses is to make the student practically acquainted with the science, so that he may conduct chemical analysis and original research, and generally to fit him for applying the science to the Arts, Manufactures, and Agriculture. The courses are also suitable for students preparing for their medical and pharmaceutical examinations. A three months' course of Practical Chemistry for the B.Sc., Edinburgh, in the department of Public Health, may be taken in the College Laboratory.

The Laboratory will be open for students daily from 9 a.m. to 4 p.m., except on Saturdays, when it will be closed at 3 p.m. Each student on entering will be allowed to arrange his working hours to suit his own convenience, but will be required to keep the hours when once fixed.

Sessional Fees for Day Students:—The fees for both sessions are—for six hours per week, £3 3s.; each additional hour per week, 10s. 6d. Day students may not enter for less than six hours a week. Students joining the Laboratory during the second term will be charged two-thirds, and during the third term one-third of the above fees. Students may also enter for short periods, working every day in the week at the following fees:—For one month, £2 12s. 6d.; for two months, £5 5s.; for three months, £7 7s.

Evening Classes.—Courses of Lectures and Practical Laboratory instruction.

UNIVERSITY OF EDINBURGH.

Professor.—A. Crum Brown, F.R.S.E.

Two degrees in Science are conferred by the University of Edinburgh, viz., Bachelor of Science (B.Sc.) and Doctor of Science (D.Sc.). Both these degrees are conferred in Physical and Natural Science, in Public Health, and in Engineering.

Candidates for degrees in Physical and Natural Science must pass a preliminary examination in English, Latin, Arithmetic, the Elements of Mathematics, and the Elements of Mechanics, and in at least two of the following subjects:—Greek, French, German, Higher Mathematics, Natural Philosophy, Logic, and Moral Philosophy.

The First B.Sc. Examination embraces Mathematics, Natural Philosophy, Chemistry, Zoology, including Comparative Anatomy, and Botany. The Second B.Sc. Examination the Higher Mathematics, Experimental Physics, Chemistry, Zoology, Botany, Physiology, and Geology, including Palæontology and Mineralogy.

The D.Sc. Examination embraces Mathematics, Natural Philosophy, Applied Mathematics, Experimental Physics, Practical Astronomy, Chemistry, Zoology and Comparative Anatomy, Animal Physiology, Botany, and Geology, including Palæontology and Mineralogy.

GLASGOW AND WEST OF SCOTLAND TECHNICAL COLLEGE.

The main objects of this College are to afford a suitable education to those who wish to qualify themselves for following any industrial profession or trade, and to train teachers for technical schools. It was founded by an Order in Council, dated 26th November, 1886, according to a scheme framed by the Commissioners appointed under the provisions of the Educational Endowments (Scotland) Act, whereby Anderson's College, the Young Chair of Technical Chemistry in connection with Anderson's College, the College of Science and Arts, Allan's Glen's Institution, and the Atkinson Institution were placed under the management of one governing body.

The Diploma of the College will be awarded to Day Students who have attended the courses of instruction and passed the necessary examinations. The ordinary courses will extend over three years, but arrangements will be made for advanced students continuing their studies in special departments.

The Chemical Laboratory (Prof. Dittmar's) opened on September 3rd. The Lecture Courses commence on October 1st.

Copies of the Calendar for 1888-9 may be had from Mr. John Young, B.Sc., the Secretary, 38, Bath Street, Glasgow, price, 1s.

The Courses of Lectures, &c., are given at various places as follow:—

ANDERSONIAN BUILDINGS, GLASGOW.

Professor of Chemistry.—William Dittmar, LL.D., F.R.S.S. Lond. and Edin.

Chief Assistant.—Archibald Kling, F.I.C.

Laboratory Assistants.—Frank Lyall, James Robson, and William Cullen.

Junior Assistants.—Andrew Reid and Andrew Hodge.

A Course of Experimental Lectures on Chemistry: Daily from 10 to 11. The Lectures up to the end of the year are devoted to an Elementary Exposition of the Philosophy and the Methods of the Science, as illustrated by the History of the Non-metallic Elements. The rest of the Session is divided between the Chemistry of the Metals and Organic Chemistry, select chapters. In addition to occasional extemporised examinations during class hours, five written examinations are held during the Session, on Saturdays from 10 to 12. Fee, £2 2s.

The Laboratory is open daily (Saturdays excepted) from 10 to 5. Advanced students may obtain permission to work privately on Saturdays also until 1 p.m. The teaching is conducted on the tutorial system, each student working by himself, at a separate place, and on his own subject. Hence students of any grade of advancement may enter at any time, and the course of instruction can be adapted to the special requirements of the individual. Original research is not forgotten, but the Professor makes it a strict rule not to use his students as his private assistants in connection with his own in-

vestigations, and rather to discourage original research with students who have not yet obtained a sufficient mastery of all the practically important methods of chemical analysis and of preparative chemistry. Fee per month, £2 2s.; due in advance. For any period of six months or more, if paid in advance, at the rate of £1 15s. per month. The fees include the use of all the ordinary reagents, and of the resources of the laboratory generally; but the student has to find his own small apparatus (test-tubes, beakers, &c.), and also a few of the more expensive reagents—e.g., chloride of platinum, nitrate of silver, molybdate of ammonia.

Supplementary Courses of Lectures and Laboratory Instruction are also given by the Assistants under the superintendence of the Professor.

THE "YOUNG" CHAIR OF TECHNICAL CHEMISTRY, YOUNG LABORATORY BUILDINGS.

Professor.—Edmund J. Mills, D.Sc. (Lond.), F.R.S.
Assistant.—Mr. William Baird.

This Chair has for its object the instruction of Students in Chemistry as applied to the various branches of industry in Chemical and other works.

LECTURES.—*Principal Course.*—A Course of Twenty-four Lectures will be delivered on Mondays and Tuesdays, at 3 p.m., commencing on October 1st. These Lectures will refer mainly to the application of higher Chemistry, and are more especially intended for manufacturers, inventors, chemical engineers, and senior chemical students. Fee for the Course, One Guinea.

Subsidiary Course.—A subsequent Course of Twenty-one Lectures will be delivered on Mondays, Tuesdays, and Wednesdays, at 3 p.m. This Course is more particularly intended for Dyers, Colour Manufacturers, Brewers and Distillers, Tar Rectifiers, Drysalterers, and others interested in a knowledge of Technical Organic Chemistry. Fee for the Course, £1 1s.

Evening Courses.—There will be a special evening course of twenty-four lectures on Bleaching, Dyeing, and Printing, commencing on October 1st.

There will be Practical Evening Classes in the following subjects:—Oils, Paints, and Varnishes; Bleaching, Dyeing, and Printing, &c.

Laboratories.—The Laboratories are open daily from 10 to 4, and on Saturday from 10 to 1 o'clock for practical working by the Students, under the superintendence of the Professor and his Assistants.

The Fee for attending the Laboratories is £20 per Session of Nine Months, £14 ros. for Six Months, £7 ros. for Three Months, or £2 ros. per month.

Inventors, Patentees, and others whose investigations require isolation and privacy, as well as professional advice, can have Private Laboratories placed at their disposal. Electric Cable has been laid to these laboratories for the supply, if required, of adequate power.

Agricultural Chemistry.—Mr. C. M. Aikman, M.A., B.Sc., &c., will give courses of Evening Lectures on this subject. Elementary, Tuesdays, at 7. Senior, Fridays, 7 to 9.

Further information may be obtained of the Professor, at the Young Laboratory, 60, John St., Glasgow.

SCIENCE AND ART BUILDINGS.

Metallurgy and Mineralogy.—Professor, A. Humboldt Sexton, F.R.S.E., &c. Assistants: J. Morrow Campbell, B.Sc., and R. Law.

A course of lectures on Metallurgy on Mondays, Wednesdays, and Fridays, at 10 o'clock. Fee, £2 2s.

The Metallurgical Laboratory is open daily from 10 to 1.30. Instruction is given in all branches of practical Metallurgy and Assaying. Fee for the session, £6 6s.

A course of instruction in Mineralogy, including the use of the blowpipe, &c., is given on Tuesdays and Thursdays from 12 to 1. Fee, £1 1s.

Evening classes in Chemistry, Metallurgy, and Mineralogy commence on Monday, October 1st.

UNIVERSITY OF ST ANDREWS.

UNITED COLLEGE OF ST. LEONARD AND ST. SALVATOR.

Professor of Chemistry.—T. Purdie, B.Sc., Ph.D., Assoc. R.S.M.

The Session begins on October 30th. A Competitive Examination, open to intending Students of Arts or Science, for fifteen Entrance Bursaries, ranging in value from £30 to £10 each per annum, will be held on Friday and Saturday, October 26th and 27th. Two Degrees in Science are conferred by the University of St. Andrews, viz., Bachelor of Science (B.Sc.) and Doctor of Science (D.Sc.), the regulations regarding which will be found in the "University Calendar."

Lecture Course.

A Lecture is delivered by the Professor of Chemistry, at 11 o'clock, on five days in the week throughout the Winter Session. The Course commences with the study of a few typical substances, forming an introduction to the discussion of Chemical Theory; the Non-metallic and Metallic Elements, with their chief compounds, are then considered; and the latter part of the Course is devoted to Elementary Organic Chemistry. Three Lectures weekly are of an elementary character, and are intended to be useful to Students of Arts who desire to study Chemistry as a branch of general education, or with the view of teaching it in schools; the remaining two Lectures weekly constitute a Supplementary Course, framed so as to meet the additional requirements of Candidates for the Degree of Bachelor of Science and of Medical Students.

Certificates are awarded on the results of separate examinations on the subjects of the general and supplementary Lectures.

Fee for the Session, £3 3s.

Laboratory Course.

A class in Practical Chemistry meets for two hours weekly, to which Students attending the Lectures are admitted without additional fee. The Course consists of a series of qualitative and quantitative experiments, designed to give the Student a practical acquaintance with the principles of Chemistry regarded as a subject of general education.

The Laboratory is also open during the Session from 10 a.m. to 4 p.m., for instruction in Chemical Analysis. The fee is £10 ros. for the Session. Shorter Courses of Practical Chemistry will be arranged to meet the requirements of Students who cannot give so much time to the subject, the fees for which vary according to the number of hours taken weekly.

Several free places in the Laboratory will be given to Students desirous of engaging in original work. Applicants must satisfy the Professor that their studies are sufficiently advanced to admit of them prosecuting experimental research.

QUEEN'S COLLEGE, BELFAST.

Professor.—E. A. Letts, Ph.D., F.R.S.E., F.C.S.

I.—Chemistry.—The lectures are delivered at 3 p.m., on the first five days of each week until the beginning of April, and on two days of each week after May 1st. The course is divided into three parts:—(1) Chemical Philosophy; (2) Inorganic Chemistry; (3) Organic Chemistry.

II.—Advanced and Organic Chemistry.—Lectures on these subjects are given from the beginning of the Session, on Tuesdays and Thursdays, at 10 a.m., until the beginning of April, and at 3 p.m. after May 1st.

III.—Practical Chemistry.—In this course the Students are instructed in the general methods of conducting Chemical Analyses.

IV.—Laboratory Pupils.—The Chemical Laboratory is open from November until the beginning of April, and from May 1st until the middle of July, on the first five days of the week, from 10 a.m. until 4 p.m. Students are admitted as working pupils on payment of a fee of £5

for the first period, or of £3 10s. for the second period (or for a single term).

QUEEN'S COLLEGE, CORK.

Professor.—Maxwell Simpson, D.Sc., M.D., F.R.S., &c.
The Course is divided into Inorganic and Organic Chemistry.

In the first part are discussed the Laws of Combination and Affinity, Molecular Chemistry and Crystallography, and the History of the Non-Metallic and Metallic substances.

In the Organic portion of the Course will be considered the subjects of Organic Analysis, Organic Series, Compound Radicals and Types, Metamorphosis of Organic Bodies, History of Special Animal and Vegetable Bodies.

In treating of the Laws of Chemistry, and the History of Inorganic and Organic Bodies those points will be chiefly dwelt upon which have a practical bearing in the Arts, Medicine, Engineering, and Agriculture. Thence, during the Course, attention will be directed to the application of Chemistry to Medicine and Physiology, to Metallurgic Operations, Chemical Manufactures, Building Materials, Soils, and Manures.

Fee.—For each Sessional Course, £2. Each subsequent Course in Medicine, £1.

The Chemical Laboratory is open daily except on Saturdays, from 10 to 4 o'clock, under the Superintendence of the Professor, to Students desirous of prosecuting an extended course of qualitative and quantitative analysis, and for the purpose of original investigation in connection with the Arts, or in the higher departments of Scientific Chemistry.

ROYAL COLLEGE OF SCIENCE FOR IRELAND, STEPHEN'S GREEN, DUBLIN.

Professor of Practical and Theoretical Chemistry.—W. N. Hartley, F.R.S.

The Session commences on Monday, October 1, 1888.

The instruction comprises courses of Lectures on General, Applied, and Analytical Chemistry, and also a course of Lectures on Metallurgy.

The Chemical and Metallurgical Laboratories, under the direction of Professor Hartley, are open every week-day during the Session. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical Research. *Fee*, for the Session of nine months, £12; for six months, £9; for three months, £5; for one month, £2. *Fee* for a course of assaying not less than £5.

There are four Royal Scholarships of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to Associate Students, not being Royal Exhibitioners, who have been a year in the College on the results of their examinations. There are also nine Royal Exhibitions attached to the College, of the yearly value of £50 each, with Free Education, including Laboratory Instruction, tenable for three years; three become vacant each year, and are competed for at the May Science Examinations of the Department of Science and Art.

A Diploma of Associate of the College is granted at the end of the three years' course.

Evening Classes.—Courses of Evening Lectures are occasionally given by the Professors during the Session.

CHEMICAL LECTURES, CLASSES, AND LABORATORY INSTRUCTION.

CITY AND GUILDS OF LONDON INSTITUTE FOR THE ADVANCEMENT OF TECHNICAL EDUCATION.—*Central Institution, Exhibition Road.*—Professor of Chemistry, H. E. Armstrong, Ph.D., F.R.S. This Institution is intended to afford such practical, scientific, and artistic instruction

as shall qualify persons to become—(1) Technical teachers; (2) Mechanical, civil, and electrical engineers, architects, builders, and decorative artists; (3) Principals, superintendents, and managers of chemical and other manufacturing works. Prominent among the agencies adopted is a scheme of Technological Examinations, in connection with which a large number of classes have been instituted in the various manufacturing centres of the kingdom at which practical instruction is given in the application of Science and Art to different industries. The work done in these classes is inspected by the Institute, and, on the results of the annual examinations, certificates and prizes are granted. The Matriculation Examination will be held on Tuesday, September 25th. *Technical College, Finsbury.*—Professor of Chemistry, Raphael Meldola, F.R.S. The College fulfils the functions of a finishing technical school for those entering industrial life at a comparatively early age; of a supplemental school for those already engaged in the factory or workshop; and of a preparatory school for the Central Institution. It is under the general direction of the Principal or Superintendent of Studies. At the head of each Department is a Professor, who is assisted by one or more Demonstrators; and besides these there are Lecturers and Teachers for instruction in special subjects: Skilled Artizans are employed in the Workshops for the guidance of the Students. The Session is divided into three terms:—The Winter term commences on Tuesday, October 2nd. An examination for the admission of Students will be held at the College at 10 o'clock on Wednesday, September 26th, 1887, and the work of the Session will commence on October 4th. The instruction consists of Day and Evening Classes and Laboratory Instruction.

BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION, BREAM'S BUILDINGS, CHANCERY LANE.—*Organic Chemistry:* On October 3rd Mr. F. Gossling, B.Sc., will commence (1) at 7 p.m. a course of Elementary Lectures; and (2) at 8.15 p.m. a Course of Advanced Lectures, the latter being adapted for the preparation of Students for the final B.Sc. (London) Examination. Laboratory practice and analysis will commence on the 5th October. Courses will be conducted adapted for the Elementary, Advanced, and Honours Examinations of the Science and Art Department, and for the Pass and Honours Courses of the 2nd B.Sc. *Inorganic Chemistry:* Mr. G. Chaloner, F.C.S. Lectures—Elementary, Tuesdays, 8.30 p.m.; Advanced, Saturdays, 9 p.m.; Practical, Tuesdays, 6–8 p.m.; Thursdays, 7–9 p.m.; Saturdays, 7–9 p.m.

SCHOOL OF PHARMACY OF THE PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, 17, Bloomsbury Square.—The school opens on Monday, the 1st of October. Lectures on Chemistry and Physics, by Prof. Wyndham Dunstan, on Monday, Tuesday, and Wednesdays, at 9 a.m. Lectures on Botany by Professor Green, on Friday and Saturday mornings at 9. Demonstrations in *Materia Medica* by Mr. Holmes, Curator of the Society's Museums, on Thursdays at 10 a.m. Lectures and Demonstrations in Pharmacy and Practical Pharmacy by Mr. Ince, on Tuesday, Thursday, and Friday, at 5 p.m. The Laboratories for Practical Instruction in Chemistry as applied to Pharmacy, &c., under the direction of Prof. Attfield, assisted by Mr. F. W. Short, will be open daily at 10 a.m. throughout the Session. They are fitted up with every convenience for the study of the principles of Chemistry by personal experiment. They are specially designed for the student of Pharmacy but are equally well adapted for the acquirement of a knowledge of Chemistry in its application to Medicine, Manufactures, Analysis, or Original Research. There is no general class for simultaneous instruction, each student following an independent course of study always determined by his previous knowledge; pupils can therefore enter for any period at any date. *Fees* for the Lectures: Chemistry, First Course, £4 4s.; Second Course, £2 2s.; an entire Session—Two Courses, £5 5s. Botany—First Course, £3 3s.; Second Course, £2 2s.; Session, £4 4s. Pharmacy—One Course, £2 2s. For Practical Chemistry,

10 months, 12 to 25 guineas, according to hours of attendance. *Council Prizes*.—At the end of the First or Winter Course a Bronze Medal and two Certificates of Honour, and at the close of the Session a Silver Medal and three Certificates of Honour are offered for competition by the Council. In the Class of Practical Chemistry, a Silver Medal, Bronze Medal, and five Certificates of Honour, are offered by the Council for competition. In the Materia Medica and Pharmacy Classes a Bronze Medal is offered for competition at the end of each Course, and a Silver Medal at the end of the Session.

CHARTERHOUSE SCIENCE AND ART SCHOOLS.—Classes are established in this institution by which instruction of a practical character is given in most of the Sciences at a very nominal fee; whilst in Art, at an equally low rate, Students, under the direction of five competent instructors, can be advanced in their studies. Those who have leisure can, at a very moderate charge, attend the Day Classes in Art. Day Classes will also be held to prepare Candidates for Matriculation (Lond.), the Clerical, Medical (including Dental), Legal, and other Examinations. Students who aim at becoming proficient in Chemistry (Organic and Inorganic) have the opportunity of working in a well-fitted Laboratory, capable of accommodating sixty Students. Aspirants of University Honours can at a small expense be assisted in their studies.

THE CITY SCHOOL OF CHEMISTRY AND PHARMACY, 27, Chancery Lane, London, W.C.—Principal, Mr. Maurice Williams. Theoretical and Practical Chemistry, Chemical Physics, Theoretical and Practical Pharmacy, Materia Medica, Therapeutics, and Toxicology.

NEW CENTRAL SCHOOL OF CHEMISTRY AND PHARMACY, 173, Marylebone Rd., London.—Mr. J. Woodland, F.C.S., In addition to the usual Chemical studies, Special Instruction Classes are held for Students of Medicine.

SOUTH LONDON SCHOOL OF PHARMACY, 325, Kennington Road, S.E.—This School opened on September 12th, and the Session lasts until July 15th, 1889. Lectures on Chemistry and Physics, by Dr. John Muter, F.R.S.E., F.I.C., Daily, at 9 a.m. (Organic) and 10 a.m. (Inorganic). Lectures on Botany daily at 12 noon, and at 2 p.m. on Materia Medica and Pharmacy, by Mr. Dodd, F.C.S. The Laboratories for Qualitative and Quantitative Analysis open daily from 9 till 5, under the direction of Mr. de Koningh, F.I.C., F.C.S., assisted by Mr. Armstrong. The Students' Laboratory of this Institution is specially designed to accommodate 40 Students. The Technical Laboratory is open daily from 9 till 4, and is fully fitted with all apparatus for teaching the manufacture of drugs and chemicals. Periodical Examinations of the Students are held by Visiting Examiners appointed by the Council of Education, and Medals and Certificates are awarded on the results thereof. Fees for the first three months £10 10s. (junior) and £12 12s. (senior); afterwards £2 2s. and £3 3s. per month respectively, inclusive of all departments. Technical Laboratory, £3 3 per month extra.

ONSLow COLLEGE OF SCIENCE, 183, King's Road, Chelsea, S.W.—Lectures and Laboratory instruction in Chemistry and Pharmacy. Special Evening Classes in Inorganic and Organic Chemistry, &c. The Chemical and Metallurgical Laboratories are open every day and evening for practical work. Principal, Mr. W. H. Martin.

ROYAL VICTORIA HALL, Waterloo Bridge Road, S.E.—Science and Technical Classes, Session 1887-88. Lectures will be given in the following subjects:—Electricity and Magnetism, Mr. L. H. Owen; Animal Physiology, Dr. Drew, B.Sc.; and Chemistry, Dr. Forster Morley and Mr. E. E. Graves. Classes are also held in Mathematics, Plane and Solid Geometry, Machine Construction and Drawing, Applied Mechanics, Shorthand, and Arithmetic. The instruction given is suited to artisans and practical men, and is chiefly in connection with the Science and Art Department, South Kensington.

PORTMAN SCHOOL OF PHARMACY, 156, Marylebone Road, Regent's Park.—Principal, Mr. F. H. Painter.

WESTMINSTER COLLEGE OF CHEMISTRY AND PHARMACY, Trinity Square, Borough, S.E.—Messrs. Wills and Wootton.

BRISTOL MEDICAL SCHOOL.—Mr. T. Coomber, F.C.S. **INSTITUTE OF CHEMICAL TECHNOLOGY**, Hacksins Hey, Liverpool.—Principal, Mr. A. Norman Tate, F.I.C. The course of instruction is intended more especially for students who wish to gain a knowledge of chemistry and the allied sciences in their relation to industrial and commercial pursuits, and embraces a thorough preliminary course of theoretical chemistry and practical laboratory work, followed by instruction in chemical technology fitted to the requirements of each pupil. In addition to these chemical studies, students who desire it can enter upon a special course calculated to afford them knowledge useful in the erection and arrangement of manufactories and plant, and construction of apparatus.

LEEDS SCHOOL OF MEDICINE.—Prof. Smithells.
LEEDS SCHOOL OF SCIENCE AND TECHNOLOGY.—Mr. J. Wertheimer, B.Sc., F.C.S., and Mr. E. Rawlins, F.C.S.
NEWCASTLE-ON-TYNE SCHOOL OF SCIENCE AND ART AND TECHNICAL COLLEGE (Chemical and Metallurgical Department).—Principal, P. Hawkrigge, B.A. Lecturers and Demonstrators, W. D. Oliver, H. Oliver, J. D. Best, &c. Classes will be held in the Day School and in the Evening Classes in all stages of Inorganic and Organic Chemistry, and the Laboratories will be opened for practical work, including Qualitative and Quantitative Analysis. Classes will also be held in Metallurgy, both Theoretical and Practical.
SHEFFIELD BROUGH ANALYSTS' LABORATORY, 1, Surrey Street.—Mr. A. H. Allen, F.C.S. Day and Evening Classes.
SHEFFIELD MECHANICS INSTITUTION, Tudor Street.—Lecturer on Chemistry, Henry J. Hardy, F.C.S., &c. The Course is divided into Organic and Inorganic Chemistry. About 30 Lectures are given in each. The Session commenced September 10th.

UNIVERSITY OF ABERDEEN.—Mr. J. S. Brazier, F.C.S. SCHOOL OF MEDICINE, SURGEON'S HALL, EDINBURGH.—Dr. Stevenson Macadam, F.R.S.E., Mr. Falconer King, Mr. Ivison Macadam, and Mr. Drinkwater.
EDINBURGH SCHOOL OF PHARMACY AND CHEMISTRY.—The instruction qualifies for graduation in Medicine and Science in the University of Edinburgh and other Examining Boards. Secretary, Mr. R. Urquhart.
EDINBURGH SCHOOL OF MEDICINE, 41, Chambers St.—Dr. Drinkwater, F.C.S.—The instruction here qualifies for all Medical Boards, Edinburgh University, London University, &c. Day and Evening Classes.
MINTO HOUSE MEDICAL SCHOOL, CHAMBERS STREET, EDINBURGH.—Mr. J. Falconer King, F.I.C., F.C.S. Lectures and Classes.
NEW VETERINARY COLLEGE, LEITH WALK, EDINBURGH.—Professor Ivison Macadam.
GLASGOW UNIVERSITY.—Prof. J. Ferguson.
GLASGOW VETERINARY COLLEGE.—Professor Cooke.
SCHOOL OF CHEMISTRY, 138, Bath Street, Glasgow.—Dr. Wallace, Mr. Tatlock, and Dr. Clark. Day and Evening Classes.
CHEMICAL LABORATORIES AND CLASS ROOMS.—Messrs. R. R. Tatlock and Readman, City Analyst's Laboratory, 156, Bath Street, Glasgow; and India Buildings, Edinburgh. Winter Session from October to March, and Summer Session from May to July, inclusive. Hours of attendance in Laboratory from 10 till 4 daily. Courses of Lectures will be delivered on the laws and principles of Chemical Science and Laboratory Practice during the Winter Session. Evening Class for Commercial Analysis on Monday Evenings from 7 to 9, beginning on October 8.
ROYAL INFIRMARY MEDICAL SCHOOL, 86, Castle Street, Glasgow.—Chemical Department: Dr. Milne, F.I.C. The Winter Session for Practical Chemistry begins on October 1st, and the Course of 100 Lectures on Inorganic and Organic Chemistry on October 28. Syllabuses of Day and Evening Courses of instruction may be had on application.

QUEEN'S COLLEGE, GALWAY.—Dr. T. H. Rowney.
ROYAL COLLEGE OF SURGEONS IN IRELAND, DUBLIN.—Professor of Chemistry and Hygiene: Sir Charles A. Cameron, M.D., F.R.C.S.I. Instruction is given in the College Laboratory in General, Practical, and Analytical Chemistry, and in the subjects (Physical, Chemical, and Microscopical) required for Examinations in Public Health and to educate for the position of Public Analyst.
NORTH CITY SCHOOL OF SCIENCE AND TECHNOLOGY, Mechanics' Institute, Lower Abbey Street, Dublin.—Evening Classes: Mr. Clement J. Leaper.
DUBLIN, CARMICHAEL COLLEGE OF MEDICINE.—Professor of Chemistry: C. R. C. Tichborne, Ph.D., F.C.S.
DUBLIN, CATHOLIC UNIVERSITY.—Dr. Campbell.

CHARLES GRIFFIN & CO.'S LIST.

By A. WYNTER BLYTH, M.R.C.S., F.C.S.,
Public Analyst for the County of Devon.

New and Revised Edition, Crown 8vo., cloth. 16s.

FOODS: THEIR COMPOSITION AND ANALYSIS.

"Will be used by every Analyst."—*The Lancet*.

"* The New Edition contains many Notable Additions, especially on the subject of MILK and its relation to FEVER-EPIDEMICS, the PURITY of WATER-SUPPLY, the new MARGARINE ACT, &c.

POISONS: THEIR EFFECTS AND DETECTION. 16s. SECOND EDITION.

"A sound and practical Manual of Toxicology, which cannot be too warmly recommended. One of its chief merits is that it discusses substances which have been overlooked."—*Chemical News*.

HYGIENE AND PUBLIC HEALTH (A DICTIONARY OF). With Illustrations. 28s.

"A work of extreme value."—*Medical Times and Gazette*.

By MM. PHILLIPS and BAUERMAN.

ENLARGED AND REVISED EDITION. In Royal 8vo., with Numerous Illustrations. 36s.

ELEMENTS OF METALLURGY: a

Practical Treatise on the Art of Extracting Metals from their Ores. By J. ARTHUR PHILLIPS, C.E., F.R.S., F.C.S., F.G.S., Ancien Elève de l'École des Mines, Paris. Rewritten and Edited by the Author, and by H. BAUERMAN, F.G.S.

CONTENTS.—Refractory Materials—Fire-clays—Fuels, &c.—Antimony—Arsenic—Zinc—Iron—Cobalt—Nickel—Mercury—Bismuth—Lead—Aluminium—Copper—Tin—Gold—Silver—Platinum, &c.

"The value of this work is almost inestimable."—*Mining Journal*.

"* Many NOTABLE ADDITIONS will be found in the sections devoted to IRON, LEAD, COPPER, SILVER, and GOLD, dealing with new Processes and Developments.

By Prof. A. HUMBOLDT SEXTON, F.I.C., F.C.S.,
Glasgow and West of Scotland Technical College.

OUTLINES OF QUANTITATIVE ANALYSIS. For the Use of Students. With Numerous Illustrations. SECOND EDITION. Crown 8vo., cloth. 3s.

"A good and useful book. . . Really supplies a want."—*Lancet*.

"Well adapted for Students. . . The directions are both simple and clear. . . Will be welcome to many teachers of Practical Chemistry, for the PROCESSES ARE WELL CHOSEN and the PRINCIPLE UNDERLYING EACH METHOD IS ALWAYS CLEARLY EXPLAINED."—*British Medical Journal*.

OUTLINES OF QUALITATIVE ANALYSIS. For the Use of Students. With Numerous Illustrations. Crown 8vo., cloth

[Immediately.]

By Drs. DUPRÉ and HAKE.

In Crown 8vo., cloth. 7s. 6d.

A SHORT MANUAL OF INORGANIC

CHEMISTRY. By A. DUPRÉ, Ph.D., F.R.S., F.C.S., and H. WILSON HAKE, Ph.D., F.I.C., F.C.S., of the Westminster Hospital Medical School. With a Coloured Plate of Spectra.

"A well-written, clear, and accurate Elementary Manual of Inorganic Chemistry. . . We agree heartily in the system adopted by Drs. Dupré and Hake, WILL MAKE EXPERIMENTAL WORK TREBLY INTERESTING BECAUSE INTELLIGIBLE."—*Saturday Review*.

"By a LONG WAY THE BEST of the small Manuals for Students."—*Analyst*.

By WILLIAM STIRLING, M.D., Sc.D.,
Brackenbury Professor of Physiology and Histology, Victoria University.

Crown 8vo., cloth. 8s. 6d.

PRACTICAL PHYSIOLOGY (OUTLINES

OF). Including EXPERIMENTAL and CHEMICAL PHYSIOLOGY. A Laboratory Handbook for the Use of Students. With 142 Illustrations.

"An excellent treatise, which we can thoroughly recommend."—*The Lancet*.

Demy 8vo., with Diagrams and Specimens, cloth. 21s.

DYEING AND DYEING RECEIPTS

(A MANUAL OF). By JAMES NAPIER, F.C.S., F.R.S.E. "EXCEEDINGLY VALUABLE to the Practical Dyer. . . A Manual of necessary reference to all who wish to keep pace with the scientific discoveries of the time."—*Journal of Applied Science*.

London: CHARLES GRIFFIN & CO.,
EXETER STREET, STRAND.

MESSRS. WHITTAKER'S BOOKS.

MANAGEMENT OF ACCUMULATORS AND PRIVATE ELECTRIC LIGHT INSTALLATIONS. A Practical Handbook by Sir DAVID SALOMONS, Bart., M.A. Fourth Edition, Revised and Enlarged, with 32 Illustrations. Cloth, 3s.

"To say that this book is the best of its kind would be a poor compliment, as it is practically the only work on accumulators that has been written."—*Electrical Review*.

ELECTRICAL INSTRUMENT-MAKING FOR AMATEURS. A Practical Handbook. By S. R. BOTTONE, Author of "The Dynamo," &c. With 60 Illustrations. Second Edition. Cloth, 3s.

ELECTRIC BELLS. A Practical Handbook for Amateurs. By S. R. BOTTONE. [Immediately.]

ON THE CONVERSION OF HEAT INTO WORK. A Practical Handbook on Heat-Engines. By WILLIAM ANDERSON, M.Inst.C.E. With 61 Illustrations. Pp. viii.-254. 6s.

SEWAGE TREATMENT, PURIFICATION, AND UTILISATION ; A Practical Manual for the Use of Corporations, Local Boards, Officers of Health, Inspectors of Nuisances, Chemists, Manufacturers, Riparian Owners, Engineers, and Ratepayers. By J. W. SLATER, F.E.S., Editor of *Journal of Science*. Crown 8vo., cloth, price 6s.

London: WHITTAKER AND CO.,
Paternoster Square.

BOOKS FOR SCIENCE STUDENTS.

ATTFIELD'S CHEMISTRY: General, Medical, and Pharmaceutical; including the Chemistry of the British Pharmacopœia. Eleventh Edition. Illustrated. 15s.

FRANKLAND'S LECTURE NOTES FOR CHEMICAL STUDENTS. Sixth Thousand. Vol. I. (Inorganic), 4s. Third Edition. Revised by Dr. JAPP, M.A. Vol. II. (Organic), 6s.

CHURCH'S LABORATORY GUIDE FOR STUDENTS OF AGRICULTURAL CHEMISTRY. Sixth Edition, Revised. 6s. 6d.

GUTHRIE'S ELEMENTS OF HEAT AND OF NON-METALLIC CHEMISTRY. 7s.

GREVILLE WILLIAMS'S HANDBOOK OF CHEMICAL MANIPULATION. Illustrated. With Supplement. 15s.

HENFREY'S ELEMENTARY COURSE OF BOTANY: Structural, Physiological, and Systematic. Illustrated by upwards of 600 Woodcuts. Fourth Edition. By MAXWELL T. MASTERS, M.D., F.R.S., &c., Examiner in Botany to the University of London, and A. W. BENNETT, M.A., B.Sc., &c. 15s.

BABINGTON'S MANUAL OF BRITISH BOTANY. Eighth Edition, corrected throughout. 10s. 6d.

GRIFFITH'S ELEMENTARY TEXT-BOOK OF THE MICROSCOPE. Coloured Plates. 7s. 6d.

GRIFFITH & HENFREY'S MICROGRAPHIC DICTIONARY. A Guide to the Examination and Investigation of the Structure and Nature of Microscopic Objects. Fourth Edition. Edited by J. W. GRIFFITH, M.D., &c.; assisted by the Rev. M. J. BERKELEY, M.A., F.R.S., and Prof. T. RUPERT JONES, F.R.S. Illustrated by 53 Plates and numerous Woodcuts, giving Figures of nearly 3000 Objects. £2 12s. 6d.

WINKLER'S HANDBOOK OF TECHNICAL GAS-ANALYSIS. Containing Concise Instructions for carrying out Gas Analytical Methods of Proved Utility. Translated by Prof. LUNGE. With numerous Illustrations. 7s.

Lo don: GURNEY & JACKSON, 1, Paternoster Row
Successors to Mr. VAN VOORST.

MESSRS. BELL'S BOOKS.

ELEMENTARY PHYSICS, Examples and Examination Papers in Statics, Dynamics, Hydrostatics, Heat, Light, Chemistry, Electricity, London Matriculation, Cambridge B.A., Edinburgh, Glasgow, South Kensington, Cambridge, Junior and Senior Papers, and Answers. By W. GALLATLY, M.A., Pembroke College, Cambridge. Crown 8vo. 4s.

STÖCKHARDT. EXPERIMENTAL CHEMISTRY. A Handbook for the Study of the Science by Simple Experiments. Edited by C. W. HEATON, F.C.S. With Index and numerous Woodcuts. New Edition, Revised throughout. 5s.

COAL-TAR COLOURS, The Chemistry of. With Special Reference to their Application to Dyeing, &c. By Dr. R. BENEDIKT, Professor of Chemistry in the University of Vienna. Translated from the German by E. KNECHT, Ph.D., Head Master of the Chemistry and Dyeing Department in the Technical College, Bradford. 5s.

DYEING AND TISSUE-PRINTING. By WILLIAM CROOKES, F.R.S., Pres.C.S. 5s.

CHEVREUL ON COLOUR. Containing the Principles of Harmony and Contrast of Colours, and their Application to the Arts; including, Painting, Decoration, Tapestries, Carpets, Mosaics, Glazing, Staining, Calico-Printing, &c. Third Edition, with Introduction, Index, and several Plates, 5s. With an additional series of 16 Plates in Colours, 7s. 6d.

THE ALKALI-MAKERS' POCKET-BOOK. Tables and Analytical Methods for Manufacturers of Sulphuric Acid, Nitric Acid, Soda, Potash, and Ammonia. By GEORGE LUNGE, Ph.D., Professor of Technical Chemistry, Zurich; and FERDINAND HURTER, Ph.D. Crown 8vo., 7s. 6d.

"It is a work which must of necessity find a place on the shelves of every chemist dealing with the subject."—*The Analyst*.

London: GEORGE BELL and SONS,
York Street, Covent Garden.

TEXT-BOOKS ON CHEMISTRY

ADAPTED FOR THE

South Kensington, the Pharmaceutical Society's, and
the London University Examinations.

INORGANIC CHEMISTRY. By Professor T. E. THORPE, Ph.D., F.R.S.E., Yorkshire College of Science, and Examiner to the University of London. With numerous illustrations, copious index, and examination questions. Vol. I., Non-Metals, 3s.; Vol. II., Metals, 3s.

INORGANIC CHEMISTRY, Twenty Lessons in. By WM. VALENTIN, F.C.S., Royal College of Chemistry. With illustrations. Post 8vo., cloth, with index, 2s.

INORGANIC CHEMISTRY. By Dr. W. B. KEMSEAD, F.R.A.S., Dulwich College. New Edition, revised and extended. Post 8vo., illustrated, 2s.

PRACTICAL CHEMISTRY. By J. HOWARD, F.C.S. New Edition, with Chapter on Chemical Analysis. Post 8vo., illustrated, 1s. 6d.

QUALITATIVE CHEMICAL ANALYSIS. By F. BEILSTEIN. Foolscap 8vo., cloth 1s.

WM. COLLINS, SONS, and Co. (Limited),
Bridewell Place, London, E.C., and all Booksellers.

H. K. LEWIS,
BOOKSELLER, PUBLISHER, AND EXPORTER,
136, GOWER STREET, LONDON, W.C.

Supplies books in every department of literature, Chemical and Scientific, included, at a discount of 25 per cent (with occasional exceptions) from the published prices for cash payment. A large stock also of second-hand books at further reduced prices. Book Clubs, Colleges, Libraries, &c., in all parts of the world supplied with English and foreign literature, periodicals, publications, &c., &c. Cases and parcels of books, &c., packed and forwarded by best routes. Attention is given to the prompt and careful execution of miscellaneous orders of every description. Surgical instruments, microscopes, philosophical instruments, &c., supplied at maker's prices.

FOR SALE.—THE CHEMICAL GAZETTE. Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," CHEMICAL NEWS Office, Boy Court, Ludgate Hill London, E.C.

THE CHEMICAL NEWS.

Vol. LVIII. No. 1505.

THE THEORY OF SOLUTION.*

By T. STERRY HUNT, LL.D., F.R.S.

1. THE late inquiries of Mendeleeff into the nature of solution made known by him since 1886 have deservedly attracted attention, for the reason assigned by him in a recent paper on "The Compounds of Ethyl Alcohol with Water" (*Trans. Chem. Soc.*, October, 1887, p. 778). He there observes that while "the views of chemists respecting the relations between the ordinary cases of chemical combination and the phenomena of dissolution remain still undefined, the part played by solution in nature . . . is so important that the fulness of our chemical conceptions seems to suffer from the want of clearness in the doctrine relating" to these phenomena. He adds, "without describing the methods by which I have arrived at my views on the nature of solutions, . . . I shall now state the hypothesis which is in accordance with them. Solutions may be regarded as strictly definite chemical combinations." He again insists upon "the existence in solution of definite combination," and continues, "I intend to investigate minutely solutions of low temperatures, and I expect to obtain definite compounds in the solid state, and to explain the relations of these solid compounds, which were obtained by me in 1868, and afterwards by Guthrie, who called them cryohydrates."

Believing that the presence in solutions of such definite hydrates could be detected by studying the changes in density in relation with centesimal composition, Mendeleeff has with success applied this method to the investigation of the liquids got by diluting with water both alcohol and sulphuric acid. In this way he has obtained evidence that not less than three definite hydrates of alcohol and water, represented respectively by $C_2H_6O \cdot 12H_2O$, $C_2H_6O \cdot 3H_2O$, and $3(C_2H_6O) \cdot H_2O$, may exist in solution, from which they may be separated by reduction of temperature. Of these hydrates the first is got in a solid state at -17° , and the second at a still lower temperature. He further concludes that for sulphuric acid and water there are not less than four definite compounds in which $S \cdot H_2O_4$ is combined respectively with H_2O , $2H_2O$, $6H_2O$, and $150H_2O$. Other portions of Mendeleeff's explanations apparently refer to the fact (hereafter to be noticed) that such combinations as these, in which water is the solvent, are disturbed by changes of temperature, which destroy the chemical equilibrium, but the language is somewhat obscure.

That these views lately put forth by Mendeleeff in the paper here cited in Oswald's *Zeitschrift für physikalische Chemie*, 1887, p. 379, and in various communications to the Russian Chemical Society, are considered to be important by chemists is shown by the late remark of Crompton, who probably expresses a very general opinion when he declares that as "a consequence of Mendeleeff's original treatment of the subject, our conception of the constitution of solutions has suddenly acquired a degree of precision which is altogether remarkable when the nature of the problem is considered" (*Trans. Chem. Soc.*, Jan. 1888, p. 116).

2. As a contribution to the theory of solution the writer may be permitted to recall to the notice of chemical students his essay entitled "Thoughts on Solution and the Chemical Process," published more than a third of a century since in the *American Journal of Science* for January, 1855, and the *Chemical Gazette* for the same

year, and reprinted in his *Chemical and Geological Essays* (1874 and 1878, pp. 448-452). Therein, after showing the vague and uncertain notions as to the nature of solution held by Berzelius, Dumas, and Mitscherlich, and noting that Turner and Griffin had, among others, affirmed the chemical nature of solution, the author announced as his thesis not only that solution is chemical union, but that "all chemical union is nothing else than solution. The uniting species are, as it were, dissolved in each other, for solution is mutual." The same idea was subsequently expressed in 1874 by saying, "The type of the chemical process is found in solutions, from which it is possible, under changed physical conditions, to regenerate the original species." He had already said in 1853, "Solution is the result of that tendency in nature which constantly leads to unity, condensation, and identification." And further, "Solution is chemical union, as is indicated by the attendant condensation."

In support of this doctrine it was pointed out in the essay of 1855 that "aqueous solution presents all the phenomena of chemical combination;" among which were then enumerated "homogeneousness," "more or less perfect identification of volume," "the changes of temperature which attend the process," and the "changes of colour" seen in the solution of some compounds, as in the case of the chlorides of copper and nickel. It was further noted that "the liquid state of these combinations is often an accident of temperature. Alum and the rhombic phosphate of soda [$Na_2HPO_4 \cdot 10H_2O$] are liquids at $212^\circ F.$, and the bihydrated sulphuric acid [$H_2SO_4 \cdot 2H_2O$, now cited by Mendeleeff] is a crystalline solid below $46^\circ F.$ " This was followed by an argument to the effect that the instability of some of these hydrous compounds is not to be urged against their chemical nature, "since chemical affinity may be very feeble in degree." It was further said, "the precipitation of the [hydrated] sulphates of cerium, lanthanum, and calcium from their solutions by heat, and that of most other salts by cold, is chemical decomposition."

3. The case of arsenic trichloride was then noticed, which unites with a certain amount of water, yielding a well defined solution, and subsequently, by the addition of a larger amount, is dissociated in a different sense, so as to give chlorhydric acid and arsenic teroxide, thus illustrating the theory of double decomposition. The capacity of sulphuric acid to combine with a great amount of water was next considered, Gay Lussac, it was said, having shown that this acid will absorb from an atmosphere saturated with moisture fifteen times its own weight, while, according to the investigations of J. J. Griffin (*L. E. and D. Philos. Mag.* (3), xxix., 299), the condensation which is known to attend the union of sulphuric acid with water is still perceptible with 6000 equivalents of water to one of acid. It was then added, "there appears, however, to be with many bodies a limit beyond which the affinity for water is satisfied. The liquids, being then mechanically intermixed, gradually separate by reason of their difference in density, as is observed in dilute alcohol, and probably in some saline solutions and in metallic alloys." Reference was then made to the statements on this point to be found in "Gmelin's Handbook of Chemistry" (Cavendish Society's Ed., i., p. 111) and also to some later statements with regard to the asserted separation of dilute alcohol into layers of greater or less hydration. The many alleged cases of such separations in aqueous liquids present a problem the settlement of which will constitute an important contribution to the theory of solution.

The recent studies of Traube and Neuberg (*Zeit. Physikalisch Chem.*, i., 509-515) have confirmed the previous observations of Bodländer, showing that solutions of ammonium sulphate in dilute alcohol separate spontaneously by augmentation of temperature into layers of unlike densities, the proportion of alcohol increasing and those of water and sulphate decreasing in the upper layer. Similar results were got with alcoholic solutions

* Read before the British Association, Bath Meeting, Section B.

of other sulphates, with phosphates and carbonates, and with the hydroxides of potassium and sodium.

4. The theory of solution, as put forward by the author in January, 1855, and ever since maintained by him, embraces then:—1st. The conception that in the process of aqueous solution there are formed definite compounds with water, accompanied with all the phenomena of chemical union. 2nd. That in these compounds of a single proportion of a salt or other species with many proportions of water, there are definite limits beyond which the further addition of water gives rise (A) to decomposition, involving a new arrangement of the elements of the previously united bodies (double decomposition), or (B) to simple admixtures of one definite solution or liquid species, with another less dense solution, or with water. 3rd. That these compounds are separable in a solid state by changes of temperature, or (theoretically at least) in a liquid state by the influence of gravity. 4th. That liquidity is but an accident of solution, since it is a state depending on temperature and on pressure, which state may be assumed by all species, whether elemental or compound.

Mendeleeff, who has now arrived at similar views of the nature of solution—at least so far as aqueous solutions are concerned—has contributed to the subject an important means of investigating such solutions by the study of their specific gravities in connection with their centesimal composition. He has at the same time suggested that the existence of the various hydrates in aqueous solutions should be made evident by other physical properties than density, a suggestion which has been successfully followed up by Crompton in his recent paper, already cited, on “The Electrical Conductivity of Aqueous Solutions” (*Trans. Chem. Soc.*, Jan., 1888). Therein, by his mathematical investigation of the relation between the conductivity of more or less dilute sulphuric acid and its composition, he obtains a close concordance with the results of Mendeleeff, and concludes that “the electrical conductivity of sulphuric acid, if not wholly due to, is very largely influenced by, the formation of definite hydrates in solution.” Similar conclusions are deduced by him from the application of the same method to dilute phosphoric, nitric, and acetic acids, and to the solutions of potassium and sodium hydroxides; for all the details of which, as well as for Prof. H. E. Armstrong’s appended discussion of Crompton’s results, the reader is referred to the *Transactions of the Chemical Society* as already quoted.

5. In the author’s late volume, entitled “A New Basis for Chemistry” (Boston; 1st Ed., 1887; 2nd Ed., 1888), the question of solution has been considered in several places. Thus, in Chapter II., §12, there will be found most of the citations already given from his papers of 1853, 1855, and 1874. Further on, in Chapter XII. (§§71–73), the recent views of Guthrie and of Spencer Pickering on so-called molecular equivalents are discussed together with the bodies described by the former as cryohydrates and sub-cryohydrates. These, it was said, may be regarded as “very fusible definite crystalline compounds, containing many portions of water to a single portion of a salt or alkaloid.” The author then proceeded to express his dissent from the view maintained by Guthrie that in these compounds the “constituents are not in the ratio of any simple multiple of their chemical equivalents,” saying that their composition, as was already declared of similar cases in 1867, does not present “a deviation from the law of definite proportions,” but “is only an expression of that law in a higher form.”

It was further said, “Messrs. Tilden and Shenstone, in their studies of the great solubility in water of salts when near their melting-points, have described compounds which, unlike the cryohydrates, are homogeneous liquids, containing, in the case of somewhat fusible compounds, like silver nitrate and benzoic acid, very small proportions of water; from which the experimenters are led to conjecture for bodies an indefinite solubility in water under

proper conditions of temperature and pressure.* It is, however, easy to understand from the high equivalent weights of such dense liquids (which from their viscosity are probably colloidal) that compounds with water may exist in which the proportion of the latter, though definite, is so small a fraction that it would be neglected in the ordinary processes of analysis. . . . These two cases of apparently homogeneous compounds,—on the one hand, liquids existing at high temperatures, with very small proportions, and, on the other, solids at low temperatures, with very large proportions of water,—are alike illustrations of the complex formulas and high equivalent weights which we have so long maintained.”

In connection with the studies of Tilden and Shenstone, the writer had already elsewhere recalled† the fact of the existence of combined hydrogen in many ignited bodies at the atmospheric pressure. Such are the hydroxides of barium, sodium, and potassium, and certain vitreous borates of the latter metals, long since described by Laurent, which, at a red heat and in tranquil fusion, hold an amount of hydrogen equal to 1·2 and 1·3 hundredths of water. The presence of water in talc, and even in epidote, beryl, and eucrase, is well known, while perlite and pitchstone are hydrous glasses differing from obsidian in containing three or four hundredths of water. All of these are examples of the stability at elevated temperatures of solid compounds in which water exists dissolved, that is to say, chemically combined. They differ in degree only from the hydroxide of magnesium, or from zeolites like laumontite, and salts like the efflorescent hydrated sodium carbonate and borate.

6. In the second edition of the “New Basis for Chemistry,” in a supplementary chapter, the author has discussed at some length, among other topics, the question of the dense polymeric vapour into which chemically stable liquids are transformed under pressure above the critical point of vaporisation.‡ Therein, in §120, are considered the observations of Messrs. Hannay and Hogarth published in 1880, according to whom alcoholic solutions of potassium iodide, and of the cobaltous and ferric chlorides among others, pass integrally at temperatures somewhat above the critical point of pure alcohol into dense vapours, which, in the case of the chlorides named, retain their characteristic colours; while the absorption-spectrum of cobaltous chloride, as well as that of an alcoholic solution of chlorophyll, remain unchanged above the critical point. More than this, it was observed that the dense vapour of alcohol at 300° dissolved solid potassium iodide. The critical point of alcohol they found, as a mean of many experiments, to be 234°6′, with a pressure of 65 atmospheres, which agrees closely with the previous figures of Sajotschewsky, who found 234°3′ at 62·1 atmospheres, while Ramsay and Young have more lately assigned 243° at a pressure of very nearly 63 atmospheres. Messrs. Hannay and Hogarth further observed that a saturated alcoholic solution of anhydrous calcium chloride separated at 230° into a lighter and a denser layer, which latter at 255° dissolved, but reappeared when the pressure was taken off. Regarding this they remark that “a com-

* *Philosophical Transactions*, 1884; Part I., pp. 23–36.

† Hunt, “Mineral Physiology and Physiography,” pp. 219–222.

‡ That these dense vapours are to be regarded as polymers, or in other words, as resulting from the chemical or intrinsic condensation of the normal vapours, is apparent from the early observations of Cagniard de Latour himself. Andrews, moreover, found that carbon dioxide at 60·7°, under a pressure of 223 atmospheres, is reduced to 1·47, or less than one-half of the volume which should belong to the normal gas at this temperature and pressure, according to Boyle’s law. The dense vapour of ethylic alcohol affords a more striking example of the same fact, since, according to Messrs. Ramsay and Young, a gram. of this liquid, which has at 4° a volume of 1·2403 c.c., acquires at the critical point a volume of about 3·5 c.c., so that the specific gravity of the vapour by their observation at 243° with a pressure of about 63 atmospheres, is nearly 0·28, water being 1·00. This corresponds to a four-fold intrinsic condensation, or to 4(C₂H₅O), since the normal vapour of alcohol, calculated for the above temperature and pressure, should, in obedience to the extrinsic influences of temperature and pressure, have a specific gravity of 0·0681, or one-fourth of the number observed.

bination of the chloride with part of the alcohol evidently occurs, and at a higher temperature diffusion takes place until the fluid is quite homogeneous." Similar phenomena were observed with the alcoholic solution of ferric chloride. These remarkable observations, which seem to show the integral volatilisation of solutions and their passage into dense polymeric vapours, as well as the solubility of solids in such vapours, and the separation of apparently homogeneous solutions at elevated temperatures under pressure into distinct layers of different densities, deserve more attention than they have yet received from chemists.*

7. Many points in the theory of solution are well illustrated by the example of sodium sulphate. This is found to be most soluble at 20°, when 100 parts of water dissolve 52.76 parts of the anhydrous salt, yielding a solution which possesses a certain degree of stability, and retains its liquid form at ordinary temperatures in closed vessels, but by agitation is readily changed in great part into crystals of the decahydrate, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ —having a specific gravity of 1.47 to 1.48—which contain for the 52.76 of sodium sulphate 66.80 parts of water, or more than two-thirds of the solvent liquid. This hydrate has its point of maximum solubility in water at 34°, while that for the anhydrous salt, as we have seen, is 20°. The crystallised decahydrate is slowly changed at 34° into a liquid, melting, as it is said, in its water of crystallisation. From this liquid, as from the original solution, by a reduction of temperature, or by contact with alcohol, crystals of a new compound, the heptahydrate,—

are deposited. These, which are much harder than the last, are very unstable, and, after removal from the liquid, become milk-white by a heat of 15°, or by contact with a foreign body, and are changed, with a considerable rise of temperature, into an admixture of the anhydrous and the decahydrated sulphate. This latter, in dry air at ordinary temperatures, loses its combined water, and passes into the anhydrous salt. A similar decomposition also takes place when a saturated solution of sodium sulphate is heated above 40°, crystals of the hard and very dense anhydrous salt—specific gravity 2.64 to 2.73—being deposited. These are more or less completely re-dissolved on cooling until the temperature reaches 18°, when the formation of crystals of the heptahydrate begins, and the previously separated anhydrous sulphate itself is gradually converted into the same hydrate. When a liquid containing an excess of crystals of the heptahydrate is heated to 27°, these melt, like those of the decahydrate, and the solution will then yield crystals of the anhydrous salt. From all these facts Löwel concluded, in 1856, that sodium sulphate exists in three distinct forms in aqueous solutions, namely, as a decahydrate, as a heptahydrate, and as the anhydrous salt.† The decahydrate is readily dissociated below 34° into heptahydrate and water, and above 34° into the anhydrous salt and water, while the unstable heptahydrate is itself readily transformed into an admixture of the anhydrous salt and the decahydrate. We may regard the various liquids obtained with sodium sulphate and water as liquid forms of the decahydrated, the heptahydrated, and the anhydrous sodium sulphate, intermingled with water, or at certain transition temperatures with each other. From such admixtures anyone of these sulphated species may not only separate, under slight provocation, in a crystalline form, but also under favourable conditions (which for obvious reasons are not easily attained in practice) in liquid form, under the influence of gravity, as already suggested. In this view of solution, there is not only in change of pressure (as long since shown by Sorby), but in change of temperature, in evaporation, in dilution, and in crystallisation, a constant making and unmaking of chemical species. In the

mingling of liquids, wherever change of volume is apparent, chemical change is going on. When that ceases it may be assumed that admixture takes the place of solution.

8. According to the hypothesis regarding densities which the present writer has elsewhere maintained, volume is constant, and the integral or so-called molecular weight of the species varies, not only for gases and vapours, but for liquids and solids, as the specific gravity. This molecular weight is in fact the weight of any given volume of the species in question, whether solid, liquid, or gaseous, as compared with that of an equal volume of hydrogen gas at standard temperature and pressure, and may thus, with great propriety and significance, be called the equivalent weight of the species. Hydrogen gas being thus assumed as the unit of specific gravity for all species whatever, liquid water, the commonly received unit of specific gravity, which is formed by the intrinsic condensation or polymerisation of 1192 volumes of H_2O ($=17.96$) at standard temperature and pressure, has an integral weight of $21,408=1192 (\text{H}_2\text{O})$, or in round numbers, 21,400. Comparing with this the hard and heavy anhydrous sodium sulphate ($d=2.64-2.73$), and the softer and much lighter decahydrate ($d=1.47-1.48$), we have, with $\text{O}=15.96$, for the formula $\text{Na}_2\text{SO}_4=141.84=p$, and for $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}=321.44=p$. From these data we proceed, in accordance with our hypothesis, to fix the coefficient of condensation, or of polymerisation, of the two salts, and find for the first $400(\text{Na}_2\text{SO}_4)=57.780$, which corresponds to a specific gravity of 2.65, and for the second, $98(\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O})=31,501$, which gives a specific gravity of 1.472.*

FURTHER NOTES ON DISSOCIATION BY CONTACT-ACTION.†

By the Rev. A. IRVING, D.Sc., B.A.,
Senior Science Master of Wellington College, Berks.

Two years ago, at the Birmingham meeting, I had the honour of reading a paper before this Section, in which I propounded and gave evidence for the theory which had been growing in my own mind for some years previous, as to the probable cause of the initiation of the action of gases upon one another in contact with heated and chemically inactive porous bodies, of which platinum-sponge and platinised asbestos may be considered the most familiar examples. I showed that in some cases the reaction was brought about by the contact of heated siliceous bodies, such as fragments of pumice previously cleaned by calcination. During the two years which have passed since, I have repeated most of the experiments referred to in that paper, and always with the same results. Dr. Hodgkinson, the Professor of Chemistry at the Royal Military Academy, has also described in the *CHEMICAL NEWS*, quite recently, a simple and effective modification of the experiment for exhibiting the combination of SO_2 and free O_2 in a lecture, which is very easily performed. I have done this with my own senior class, and it seems to me to bear testimony to the truth of the theoretical explanation which I ventured to put forward, from the circumstance that the experiment is so arranged that the platinum-sponge is heated outside the apparatus before the gases are brought into contact with it, plainly showing that the reaction is not due to condensation of the O_2 in the pores of the sponge previous to the heating.

Briefly stated, the theory regards the reactions (in all such cases of contact-action) as due to the increased "bombardment of the molecules" upon the solid, owing to the increase of the heated solid surface exposed,

† Read before the British Association, Bath Meeting, Section B.

added to the increased translational energy of the molecules themselves; the increased frequency of impact causing a rise of the atom-temperatures, and a corresponding increase in the intra-molecular work done (of all vibrational energy) in unit of time, as distinguished from inter-molecular or translational energy. Considering the great differences of thermal conditions in the individual molecules in any given mass of a gas, it is conceived that many of these molecules which exist for the time in a thermal condition considerably above the mean which is indicated by the thermometer, are already in such a state of intra-molecular vibrational energy that the accession of heat to them which the increased "bombardment," engenders is sufficient to cause dissociation in some cases; and this was suggested as a probable explanation of the phenomena known as the "initial temperature of dissociation," and the apparent lowering of that initial temperature by contact action. In the case of a mixture of gases, such as $\text{SO}_2 + \text{O}_2$, or $\text{NH}_3 + \text{O}_2$, or $\text{NO} + \text{H}_2$, it seems probable that the conditions required to bring about a transfer of atoms might be realised short of actual dissociation of any of the molecules, the increase of the atomic vibrational energy required being merely such as to so far weaken the bond which holds them together in the original molecule, that this weakened bond of affinity might be overcome by the counter-attraction of other loosely-held atoms of opposite electro-chemical energy. For such a condition of things the term "quasi-nascent state" was proposed. The paper was published in full in the *CHEMICAL NEWS*, and was criticised in the pages of the same periodical. My reply to those criticisms brought a private letter from the author of them, confessing that he had misunderstood the argument of my paper, and apologising for his hasty criticism, which, he said, was based on an insufficient study of it. This is the only criticism which I have met with since the paper was read; but I may say that the ideas thrown out by Prof. Williamson in his farewell address at University College seemed to me to give considerable support to the view which I have ventured to put forward.

In my work on "Rock-metamorphism," which is now in the press, I have been led to consider the possible genesis of the great crystalline series of archæan rocks (the granitoid rocks, the gneisses, and the crystalline schists), which together make up the primordial lithosphere of the earth. In any such account as it is possible to give of their origin, on the assumption (which all the known facts seem to warrant) that the earth was once a glowing mass, it became necessary—on rejecting the fanciful notion that these primitive crystalline rocks are the results of later "regional metamorphism"—to account for the origin of the graphite in them, which geological writers have, in this country, without exception, so far as I know, assumed to be a product of extreme carbonisation of organic matter of vegetable origin; an assumption which has been one of the main props of the notion as to the origin of the primitive crystalline rocks referred to above. Now carbon (even graphitic carbon) is known to occur in meteorites, and the spectroscope has revealed the existence of hydrocarbons in the heads of comets. It is but the wildest fancy to attempt to ascribe the origin of such carbon to the carbonisation of organic matter. Reflecting upon such facts as these, and upon others well known to the chemist, as to the synthetic formation of such hydrocarbons as acetylene marsh-gas, and some others of a more complex nature through the agency of metallo-carbides, one was soon led to see that at a certain stage of the earth's development a good deal of the carbon of the original nebulous matter of the earth might easily have got hold of some of the hydrogen.

Now we know very well that some hydrocarbons can be dissociated by pure heat at the high temperature of the electric spark; and we know also that hot alkali metals, and even the glowing metal of the magnesium flame, can reduce CO_2 to elementary carbon in a very pure form; also that the most refractory hydrocarbons

can be reduced to elementary carbon by the action of dry chlorine gas upon them at red heat. It is possible that some of the graphite in the primitive archæan rocks may have been produced by any or all of these agencies. But when we note the way in which graphite occurs, often in considerable seams in those gneisses and schists, we are compelled to look about for some other cause more extensive in its operation.

The deposit of elementary carbon in the interior of the roofs of the fire-clay retorts of our gas-works is probably to be referred to the contact action of the heated porous surface of the retort upon the heavy hydrocarbons of the crude coal-gas; at least this seemed a fair deduction from the theory which I had ventured to put forward two years ago. Last May I subjected this view to the test of experiment. An ordinary combustion-tube about 9 inches long was drawn out at one end so that a continuous small flame of coal-gas could burn at it. This tube was packed with pumice fragments, which had been well-calined just before. The tube was then attached in the ordinary way by flexible tubing to the gas-pipe. The coal-gas was passed and lighted at the small end. The tube was then slowly heated by a wide Bunsen-flame. As the temperature rose to a dull red heat, dissociation of the hydrocarbons set in rapidly, and the pumice-fragments soon became coated over with a steel-grey film of elementary carbon. The tube was then detached, and after being allowed to cool while closed up it was attached to an oxygen holder, with the intervention of calcium chloride, strong sulphuric acid, and potash, to remove moisture and traces of CO_2 . The oxygen was passed for several minutes through the tube, and into lime-water, without any visible result. A small zone of the tube was then heated in a spirit-flame, and as soon as this zone was heated to a dull redness, a copious precipitation of CaCO_3 in the lime-water took place, the fragments of pumice in the heated zone being soon cleaned to their pristine whiteness.

The theory of dissociation by the contact-action of heated solids thus receives *visible demonstration in the case of hydrocarbons*. To apply this to the genesis of graphite in the primitive rocks, we have only substituted for the heated pumice-fragments in our experiment the glowing slaggy portions of the earliest crust which floated in the magma (real pumice-fragments on a grand scale); and, admitting the co-existence of hydrocarbons in the gaseous envelope which then surrounded the globe, recollecting also that the crystalline form ascribed to graphite in our text-books rarely (if ever) occurs in native graphite, we have a complete explanation of the origin of graphite in the primitive crystalline rocks without any intervention whatever of organic matter.

I have since repeated the experiment with a tube about 5 feet long, and have deposited amorphous carbon through the whole length of the tube upon the pumice, which was gradually heated from one end to the other. In a third trial the tube was heated in a gas-combustion furnace to the temperature of incipient fusion of the Bohemian glass, and the deposit was more copious than ever; but the carbon had upon the whole a more sooty appearance. This agrees with some results lately obtained by the Hon. Charles A. Parsons in some experiments on carbon at high temperatures and under great pressures, of which he gave an account in a paper read before the Royal Society in June last. Mr. Parsons informs me that he has found that the higher the temperature the soter the graphite produced, and that regardless of pressure. His experiments, however, had nothing to do with dissociation by contact action, since he started with his carbon in the elementary state.

In the second of the experiments which I have mentioned above, an accessory result was observed. As the tube was gradually heated towards the flame end, a yellowish deposit was observed in front of the flame which was applied to heat the tube. After the experiment was complete this was distilled into the drawn-out portion

of the tube, which was then cut off. On examination it was shown to be elementary sulphur by burning with a flash of blue flame, and with the smell and acid reaction of SO_2 ; while another portion of it was washed out in CS_2 , and crystallised out in the usual rhomboidal forms, as the solvent was allowed to evaporate away on a watch-glass. We have thus evidence of dissociation by contact-action of heated solids, not only of the hydrocarbons, but also of the sulphur compounds present in coal-gas.

I am of course not prepared to say that some portions of the black sooty deposit may not consist of heavy refractory hydrocarbons, as, owing to the pressure of other subjects that have engaged my attention lately, I have not made a complete combustion analysis of it, so as to determine its composition quantitatively. But even if some are present, this would not vitiate the application which I have proposed, of the theory of dissociation by contact-action to the genesis of graphite, seeing that well authenticated analyses are on record of a certain percentage of volatile hydrogenous matter in native graphite. Roth* (*e.g.*) records a case in which as much as 1.34 per cent of hydrogen was found by Cloës in a specimen of very pure Canadian graphite, and another case in which Méne found as much as 7.30 per cent of volatile matter in graphite from Passaw.

THE SOLUBILITY OF BARIUM SULPHITE IN HYDROCHLORIC ACID.

By G. STILLINGFLEET JOHNSON.

In a "Note on Barium Sulphite," published in the *CHEMICAL NEWS*, vol. lviii., p. 128, Mr. E. Rattenbury Hodges concludes that barium sulphite is not soluble in hydrochloric acid. His experimental evidence of this insolubility is, that when sulphur dioxide gas is passed into a solution of barium chloride, a precipitate is obtained which is insoluble in hydrochloric acid.

Three experiments described below throw further light upon the subject:—

I. A clear solution of barium hydrate (baryta water) is boiled to expel dissolved oxygen, and sulphur dioxide gas (obtained by the action of hydrochloric acid upon sodium sulphite) is passed into the solution. A copious precipitate results. On adding a few drops of hydrochloric acid, free from H_2SO_4 and HNO_3 , this precipitate is at once and completely dissolved.

II. A solution of barium chloride is boiled, to expel dissolved oxygen, and pure sulphur dioxide gas is passed into the solution. No precipitate is formed, or only a faint opalescence, which is not dissolved by hydrochloric acid. *Prolonged* boiling is necessary to ensure complete absence of precipitate, but saturation with the gas produces no turbidity if this precaution has been taken.

III. A solution of barium chloride, made with unboiled water, is saturated with sulphur dioxide gas. A precipitate is produced, which is quite insoluble in hydrochloric acid.

The conclusions drawn from the above experiments are as follows:—

- I. Pure barium sulphite is readily and completely dissolved by hydrochloric acid.
- II. Pure barium chloride in aqueous solution is not precipitated by pure sulphur dioxide gas.
- III. Barium chloride in aqueous solution is precipitated by sulphur dioxide in presence of dissolved oxygen, the precipitate being barium sulphate, not barium sulphite.

It will be remembered that oxygen converts $13\frac{1}{2}$ times its weight of barium sulphite into barium sulphate.

NOTE ON A TEST FOR SACCHARINE.

By DAVID LINDO.

IN the *CHEMICAL NEWS* (vol. lviii., p. 51) the author published a test for Fahlberg's saccharine, which he has since found can be modified to advantage as follows. After placing the saccharine with concentrated nitric acid in a small porcelain dish, evaporate to dryness on the water-bath, or by moving the flame of a spirit-lamp to and fro under the dish, blowing on the surface occasionally to facilitate evaporation, and taking care the heat does not rise too high. If the dish is allowed to cool and a few drops of strong solution of potash in 50 per cent alcohol are added to the residue, a faint yellow colour only will be developed. Spread the liquid over the surface of the dish, and before it has settled to the bottom, apply heat with the lamp, as above, quickly all over the under surface of the dish. If the vapour of alcohol happens to ignite it must at once be extinguished. A greater variety of colours will be developed in this way than by following the directions formerly given. As the dish cools and moisture is absorbed the colours fade; by heating they can be reproduced, but not in the same perfection as at first.

Falmouth, Jamaica, B.W.I.,

NOTE ON THE DECOMPOSITION OF NITRIC OXIDE IN CONTACT WITH WATER AND ALKALINE SOLUTIONS.

By STEPHEN COOKE, F.C.S.

PRIESTLY, in his "Experiments on Nitric Oxide," says:—"Being desirous of ascertaining whether nitrous air tended in any degree to a spontaneous decomposition by long standing only, without being in contact with any substance that could be supposed to have an affinity with any constituent part of it, I filled a large phial and corked it very tight, keeping it for the most part with its mouth immersed in a vessel of water, but neglected it and suffered the water to evaporate. However, examining the air about two years afterwards, I found it to have the same power of diminishing common air that freshly-made nitric oxide has." He, however, almost immediately afterwards mentions other experiments in which the nitric oxide appears to have undergone a change on standing a long time; but as he gives oxygen as one of the products formed, there seems to be some mistake in the experiments.

Humboldt and others declared that nitric oxide is decomposed by contact with water, with the formation of nitrate of ammonium.

Davy, however, rejects these experiments, and comes to the following conclusions as the results of his experiments:—" (1) That nitric oxide is not decomposable by water; (2) That the diminution of volume of nitrous gas placed in contact with water is owing to a simple solution of it in that fluid."

Russell and Lapraik (*Jour. Chem. Soc.*, xxiv., 37, 1876) have shown that water and nitric oxide kept at 100°C . for a fortnight, and then for four months at the ordinary temperature, had undergone a contraction of 46.7 per cent.

After making some of my experiments on nitric oxide and hydrogen in presence of platinum, an experiment was tried with the gases alone (*i.e.*, without the platinum), with the result that there was a slow but gradual contraction. On examination of the residual gases, after standing for more than twelve months, it was found that the hydrogen had no part in the reaction (except retarding it); but the nitric oxide had undergone partial decom-

position into HNO_2 and nitrogen, together with a little nitrous oxide.

Two tubes, about 0.8 metre long, were filled, one with two volumes of nitric oxide and one volume of hydrogen, the other with equal volumes of the two gases. After standing fifty-four weeks, the first had undergone a contraction of 230 m.m.; and on adding ferrous sulphate, there was a further contraction of 260 m.m., leaving 43 m.m. of nitrogen and nitrous oxide, the hydrogen being left unchanged. The liquid in the tube was strongly acid, and gave the reactions for nitrous acid. In the tube containing the larger proportion of hydrogen only 150 m.m. of gas had disappeared in the same time.

From these experiments it is evident that nitric oxide undergoes a change by merely standing in contact with water. Since these experiments were made the subject has been a little more fully investigated; tubes with platinum were used in some cases, and in others nitric oxide stood over water in tubes without any platinum.

The tubes used were about 400 m.m. long. Pure nitric oxide was used. The tubes when filled were kept standing over pure water, or in some cases over mercury with 20 or 30 m.m. of water at the top. They were kept in the dark and at the ordinary temperature.

With tubes containing platinum the contraction was gradual but slow, and for the first three or four weeks amounted to 50 m.m. per week. After about one-half has disappeared the action gets slower, and in tubes of this kind is not complete for nearly three months. The total contraction will be at least 90 per cent of the original gas. The residue is chiefly nitrogen, but it also contains a small quantity of nitrous oxide, and a portion of this gas is also found in solution. The water is acid and contains HNO_2 .

In a tube similar to the last, but containing no platinum, the action is slower—in the first month the contraction was 100 m.m., and towards the end the action is very slow indeed. In nine months the change was complete, the gas remaining being from 10 per cent to 20 per cent of the original; the nitric oxide had quite disappeared, the residue consisting of nitrogen and nitrous oxide.

In a tube containing platinum the action of heat in accelerating the change was tried. Nitric oxide was sealed up in such a tube with a little water and kept for two hours at 100°C .; there was a contraction of 20 per cent, the residue consisting of nitric oxide, nitrous oxide, and nitrogen.

It is well known that a solution of caustic potash acts gradually on nitric oxide, potassium nitrate and nitrous oxide resulting from the change. The action, however, is very slow, taking some months to complete. Russell and Lapraik have shown that the action is much accelerated by keeping at a boiling temperature. At common temperature, or at 100°C ., the action is much hastened by the presence of platinum. A tube of nitric oxide 400 m.m. long, containing platinum, was placed in a solution of caustic potash; the action was complete in three weeks, about three-fourths of the original gas disappearing. In a similar tube, sealed up and kept for three hours at 100°C ., a like change took place.—*Glasgow Philosophical Transactions*.

THE INFLUENCE OF MANGANOUS SULPHATE AND OTHER SALTS ON THE TITRATION OF IRON IN HYDROCHLORIC ACID SOLUTION BY POTASSIUM PERMANGANATE.

By DAVID L. LUKE.

The author has made a series of experiments similar to those performed by the late Dr. Clemens Zimmermann, Kessler, Thomas, and others, studying the influence of manganous sulphate and other salts on the titration of

iron in hydrochloric acid solution with potassium permanganate. His results were mainly corroborative of what these investigators have already shown.

It was found that the presence of manganous sulphate in the hydrochloric acid solution of the ferrous salt would prevent, for a short while at least, the reduction of a greater amount of potassium permanganate than corresponds to the amount of ferrous salt in solution, and also that no free chlorine was detected on titration. Lead chloride acted in a manner similar to manganous sulphate.

Magnesium, cobalt, and copper sulphates were also tried, but gave no good results, showing them to be of no value.

A very important precaution is to watch the end reaction in the hydrochloric acid solution containing MnSO_4 very closely, which can be distinguished by the first complete colouration throughout the liquid. If not stopped there too much permanganate can be easily added, because of the almost immediate fading out of the colour of the first few c.c. added after the end reaction was reached.

The solutions used were similar to those of Zimmermann. Hydrochloric acid = 1.12 sp. gr., H_2SO_4 = 1.84 sp. gr., a dilute solution of permanganate, with a titre of 0.0039603 Fe, and a stronger one of 0.0081136 Fe. Manganous sulphate solution 200 grms. in 1 litre. Also a hot saturated solution of lead chloride.

(1). The first experiments were with ferrous ammonium sulphate, and gave the following results:—

No.	$\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 + 6\text{H}_2\text{O}$ Grm.	H_2SO_4 C.c.	HCl. C.c.	MnSO_4 C.c.	$\text{K}_2\text{Mn}_2\text{O}_8$ C.c.

5.	100	40	20	37.80

A similar hydrochloric acid solution of magnetite was made, reduced with zinc, and titrated with the same permanganate solution.

No.	Iron Solution. C.c.	H_2SO_4 C.c.	MnSO_4 C.c.	$\text{K}_2\text{Mn}_2\text{O}_8$ C.c.
1.	50	—	—	38.00
2.	50	10	20	37.50
3.	50	10	20	37.50
4.	50	10	20	37.45

A ferro-manganese dissolved in hydrochloric acid and titrated twice in presence and twice in absence of manganous sulphate, gave each time the same result on titrating. It should be said that the ferro-manganese contained about 65 per cent manganese and 30.4 per cent iron.

N. Wiley Thomas's method consists in substituting lead chloride for manganous sulphate, and proceeding as before. A quantity of magnetite was therefore dissolved by the author in hydrochloric acid, and titrations were made in presence of lead chloride, also manganous sul-

phate, and alone. The lead chloride was added as a hot saturated solution.

6.	25	—	20	15'55

From the above results it will be observed that under the proper conditions, *i.e.*, in presence of either manganous sulphate or lead chloride, Margueritte's method for the titration of iron will work in hydrochloric acid solution as well as in sulphuric acid.—*Journal of Analytical Chemistry*, Vol i., Part 3.

REPORT OF THE COMMITTEE*

APPOINTED FOR THE PURPOSE OF INQUIRING INTO AND REPORTING ON

THE PRESENT METHODS OF TEACHING CHEMISTRY.†

THE Committee decided at first to restrict its enquiries to the teaching of chemistry in schools. With this object, in December last they addressed the following letter to the Head Masters of Schools and the Principals of Training Colleges, both in Great Britain and Ireland, in which chemistry forms a part of the curriculum. The list of these schools was compiled from the "Educational Year-Book."

COMMITTEE ON CHEMICAL TEACHING.

Dear Sir,—At the meeting of the British Association held at Manchester in September last, Professor H. E. Armstrong, F.R.S., Mr. J. T. Dunn, Professor W. R. Dunstan, Dr. J. H. Gladstone, F.R.S., Mr. A. G. Vernon Harcourt, F.R.S., Mr. Francis Jones, Professor McLeod, F.R.S., Professor Meldola, F.R.S., Mr. Pattison Muir, Dr. W. J. Russell, F.R.S., Professor Smithells, Mr. W. A. Shenstone, and Mr. Stallard were appointed as a Committee for the purpose of inquiring into, and reporting on, the present methods of teaching chemistry.

It is felt that great difficulty exists at the present time in teaching chemistry to elementary students, owing chiefly to the absence of agreement among teachers as to the best modes of giving instruction and to the diverse views of examiners. It is hoped that an inquiry by this Committee will be valuable not only to teachers of elementary chemistry, but also to those who have the responsibility of examining in this subject. The members of the Committee venture, therefore, to hope that you will assist them by furnishing, at as early a date as possible, such a report on the chemical teaching in your school as you consider will be most likely to aid their inquiry, more particularly with regard to the following points:—

1. The objects with which chemistry should be taught in schools.
2. The difficulties that are met with in teaching, and the best way of obviating them; the influence exerted by external examiners on the character of the teaching.
3. The methods which, in your opinion, are most likely to render the teaching effective as a mental discipline, and as a preparation for subsequent instruction in the higher branches of the science or in applied chemistry.

* Consisting of Prof. H. E. Armstrong, Mr. J. T. Dunn, Prof. W. R. Dunstan (Secretary), Dr. J. H. Gladstone, Mr. A. G. Vernon Harcourt, Mr. Francis Jones, Prof. H. McLeod, Prof. Meldola, Mr. Pattison Muir, Dr. W. J. Russell, Mr. W. A. Shenstone, Prof. Smithells, and Mr. Stallard. Drawn up by Prof. Dunstan.

† Read at the British Association, Bath Meeting, Section B.

The Committee will also be greatly obliged for information on any other points directly connected with the teaching of elementary chemistry; any data with which you may favour them will be regarded as confidential, and nothing of a personal nature will be published without your previous consent.

In making any communications to the Committee, it will be convenient if you will kindly affix to the manuscript the paper which is enclosed.

I am, Sir,

Your obedient Servant,

WYNDHAM R. DUNSTAN,
Honorary Secretary to the Committee.

Five hundred copies of this letter were circulated, but only eighty-six more or less extended replies have been received; they include the majority of the largest public schools in Great Britain. These replies have been the subject of careful consideration by the Committee.

The schools which have reported represent a total number of 23,350 boys, and of these 8,418 receive instruction in chemistry; that is, 36 per cent. It will be useful to summarise in this Report, by means of extracts from typical replies, the chief points of general interest which have been alluded to, particularly those that were raised by the three questions suggested by the Committee in their letter.

I. The Objects with which Chemistry should be Taught in Schools.

There is almost unanimous agreement as to the high educational values of the science of chemistry. Teachers seem agreed that chemistry should be taught in schools with two objects: first, and mainly, on account of the mental training and intellectual discipline it affords; and secondly, for the sake of its applications in the different professions and trades which the boys may subsequently follow and also in its direct bearing on the facts of everyday life. This view of the importance of chemistry as a part of the school curriculum is well exemplified by the following extracts taken from the reports made by various schools, both large and small, and representing boys who afterwards follow a diversity of trades and professions.

I. "Chemistry should be taught in schools—(1) As an educational subject or mental discipline. In studying chemistry the pupils are led to cultivate habits of *observation*, because the statements made in chemistry are based on facts actually seen; or *reflection*, because the accurate statement of even the simplest observed fact requires not a little reflection; and of *reasoning*, because reasoning is required before one can decide that any one particular result in an experiment is due to some one particular antecedent circumstance out of several. Chemistry also is especially the science in which experiment can be most readily had recourse to by the pupil. (2) As a valuable branch of instruction. Supposing that the mental powers were not developed and strengthened by the study of chemistry, it might still be desirable that pupils should not leave our public schools wholly ignorant of the composition, properties, and uses of the materials of everyday life."

II. "Science and history alone of the subjects taught in schools perform a twofold function. They give connection of ideas, logical power, and education in the fullest sense, while at the same time they store the mind with useful facts likely to make the possessor a more valuable member of the body politic. Hence chemistry may be taught to *all* boys just in the same way as ancient languages and higher mathematics, without any thought of the future career of the pupil, or whether chemical knowledge is likely to be of practical use to him or not. In this way the practical demonstration of chemical facts becomes a great object-lesson, while chemical theory becomes an introduction to logic. Chemistry may be taught for other reasons:—(i.) To enable boys who show no special aptitude for any other subject to obtain a scholar-

ship and university education. (ii.) As a special subject, likely to be useful for those who, having passed the preliminary arts' examination, intend to adopt a medical career."

III. "The objects with which chemistry should be taught in schools:—1st. To make lads take a keener interest in natural phenomena. A few well-chosen experiments will excite their wonder, and at the same time create an interest in the secrets of nature. 2nd. To teach lads to see, *i.e.*, to develop their powers of observation. 3rd. To impress upon lads that there is a definite law of order in nature. Lads soon see that from the same bodies under similar conditions certain fixed results must follow. 4th. To make boys logical and not too hasty in generalisation from a few isolated observations. Chemistry is peculiarly well fitted for this purpose. 5th. To direct the powers of destructiveness and constructiveness which are always so pronounced in boys, since they soon learn to be interested in simplifying many complex forms and in building up others. 6th. To impress upon lads, as soon as possible, that everyday life must necessarily be influenced beneficially by a knowledge of the chemical properties of a very few simple bodies and the laws which determine their mutual interaction."

IV. "There are, I think, two considerations to be kept in view:—(a) the general educational value of the work which gives chemistry a claim to be considered a necessary part of any liberal education, whatever be the profession in view; (b) the necessity of teaching chemistry on such lines that the instruction given may be a sound and valuable apprenticeship for such boys as may be led to devote themselves specially to this subject in the future."

The following sentences (V.) were written by the head-master of one of the first public schools in England:—

V. "I think that the objects with which chemistry should be taught in schools are three:—(a) to make every boy acquainted with common scientific facts, useful to him in every branch of life. (b) To give opportunity to boys with special aptitude for science to take up and develop the study; many a boy who seems dull at languages brightens over science. (c) To enlarge the mind by the suggestion of new methods and processes and by the illustration of the mode in which nature works."

VI. "I have found that the teaching of chemistry, besides its direct value for professional and business purposes, is of great importance as a means of developing the minds of boys who have no aptitude for other subjects. I have found that many boys who cannot get on at classics and mathematics take an interest in and learn chemistry, thus being greatly encouraged in their other work by the knowledge that there is something that they can do."

VII. "Chemistry should be taught chiefly for mental discipline. Practical chemistry is almost the only school subject in which hands and brains are equally employed."

VIII. "In schools chemistry, like other subjects, is, no doubt, taught with a double view—mental training and the imparting of valuable knowledge. As to the former of these, the subject is not, in the opinion of the present writer, of great value, for the methods of demonstration as they can be exhibited in a school laboratory are not very rigorous and logical, and at the best seem rather to afford a strong presumption than a satisfactory assurance in favour of any particular conclusion. As to the latter object, it may be said that it is not one about which educationists generally are very enthusiastic. At the same time, if there is any subject more than another the knowledge of which is desirable it is chemistry. The entire change of mental attitude towards physical surroundings, which even the slightest knowledge of the principles of chemistry induces, is most noticeable, and boys find it both a source of healthy wonder and, though they do not observe it themselves, a great mental stimulus. There is, of course, one other object with which chemistry may be taught, namely, for the sake of those who will find it directly useful in after life. But as they are, after all,

only a small percentage of the whole, the argument of practical utility is one which cannot be advanced as in itself a justification for teaching the subject."

IX. "Chemistry should be taught in schools while boys are comparatively young, in order that those who have no taste for classics may find some work in which they can take a practical interest. There are boys who, without being stupid, have no taste whatever for books, and the chance of practical work, like chemistry, for which they can see some use of an obvious kind, may prevent many a boy from becoming a confirmed idler. The study of chemistry, therefore, should be encouraged as a distinct benefit to the character of many boys. It should also be encouraged for the public good, because any boy so interested in early life may be led to devote his after years to the pursuit of scientific subjects. And again, it should be taught in schools to enable boys who go into business now very young to have some slight knowledge of scientific facts of an elementary kind while they still have time to learn."

X. "All my experience shows that even to young children chemistry may be made the threshold of the fairland of science, and that by means of it they may early acquire a profound sense of the rigorous, unyielding nature of law and of the unity in the midst of diversity which pervades the world around us. Again, as a mere discipline for the intellect, I believe chemistry is destined to take the place of Latin and Greek grammar, when a definite course of teaching has been laid down, and teachers have themselves mastered that course as thoroughly as former teachers had mastered their accidence and syntax. To make the pupil aware of the existence of an unknown, unexplained, inscrutable side to every and even the simplest phenomenon, is to awaken desire, expectation, pleasure—all the antecedents of healthy mental effort, and the difference between the daily, hourly life of one who has thus become conscious of the literally infinite, ineffable nature of things around him, and that of one who thinks he knows all about them, is immense."

XI. "Too much weight may easily be attached to the objection often urged against chemical teaching (and, indeed, against the study of other branches of natural science), that it fails to cultivate good taste and good style; that the learner is brought into contact merely with material facts and not with human thoughts, and so acquires a character and mode of expressing himself as hard, rough, and unsympathising as the laws of nature with which he deals. It is certainly impossible to avoid noticing that the abstracts of lectures and answers to examination papers shown up by those who have been, or are being, well trained in "the humanities" are composed in much better style than the productions of boys who have had less advantages of the kind, or who, from their dullness in other subjects, are considered to be exactly fitted for learning natural science. But the power of refuting this objection rests with the teacher. If he refuses to pass over bad spelling and bad grammar, if he takes the trouble not merely to point out slovenliness of expression, but to show how it may be corrected, and if the learner is compelled to re-write any careless, inaccurate work in better form, there seems no reason why an account of the two oxides of carbon, including an intelligent comparison of their properties, may not be made as good an exercise in English composition as an essay on points of Greek and Roman history."

2. The Difficulties that are Met with in Teaching, and the Best Way of Obviating them; the Influence Exerted by External Examiners on the Character of the Teaching.

Much might be written about the various difficulties which are alluded to in these reports in answer to the second question suggested by the letter of the Committee. The chief difficulties are stated to be those which arise from:—(i.) Defective organisation and considerations of expense; (ii.) the lower value attached to chemistry, as

compared with other subjects of the school curriculum ; (iii.) the time which is devoted to the subject ; (iv.) preparation for various examinations ; (v.) absence of good text-books ; (vi.) dearth of properly qualified teachers.

(i.) The expenses incidental to chemical teaching and the defective organisation, which is often the result of insufficient endowment, are the subjects of general complaint. Sometimes no laboratory is provided ; frequently the laboratory accommodation is inadequate ; and it appears that the details of the preparations for lectures and practical work generally devolve on the teacher himself. The following statements may be quoted. The first two are from the reports of small schools.

XII. "We have no laboratory or other facilities for practical work, and so our experiments have to be very simple and our work very elementary."

XIII. "The chemical teaching is quite elementary, and there is no apparatus, so that it is only taken as a lesson with figures drawn and explained on the black-board."

XIV. "Thus our difficulties are :—(a) Having too many to teach. I am responsible for about 160 boys, and have no help. (b) The want of a large laboratory. We have a small but very good laboratory. There is, however, only accommodation for 12 boys, while I always have about 70 doing practical chemistry in an aggregate of six hours a week. Hence each boy gets only one hour a week. (c) The want of sufficient time to prepare for experimental work. The whole of my school time, except three hours, is taken up in teaching, so that all preparation has to be done either before or afterwards, the practical result being that I am obliged to limit my experimental teaching to the two lowest and the highest forms."

XV. "The chief obstacle to the effective teaching of chemistry here is the pooriness of the laboratory—a room in the basement, low pitched, ill lighted, and worse ventilated, accommodating only 15 boys, and in such connection with the other class-rooms as to make some of them almost unbearable when experiments are made with any foul-smelling gas." (This school contains 500 boys.)

XVI. "To lecture properly, a master must have an assistant for the experiments. I do not know what is the rule ; I hope I am an exception, for I am without one. I make use of one of the promising boys to help in the preparation preceding a lecture. This is not sufficient. A master cannot easily conduct his experiments, keep order, and carry on a judicious questioning and explanation at the same time."

XVII. "Every teacher of chemistry who has several lectures to deliver in the course of the week ought to have the services of a fairly intelligent assistant, who can get ready most of the experiments for him, or he ought to have extra time allowed him to do this himself. Of course it is possible to utilise the services of the more advanced pupils for the purpose, but this does not effect so much saving of time as might be thought, owing to the want of experience on the part of the boys, who in many cases require so much supervision that it is shorter for the teacher to do the work himself."

XVIII. "We have just abandoned the subject, owing to its ruinous expense if taught thoroughly."

XIX. "We have no laboratory, and have to do the best we can with a table in a class-room. Experiments are shown, but not performed by the boys for this reason."

XX. "Schools are often badly equipped with a suitable lecture-room, laboratory, and apparatus, partly from poverty, and partly sometimes from inability on the part of the head-master or governing body to appreciate the needs of the subject."

XXI. "Another difficulty is that in many cases the teacher has not time to prepare adequate experimental illustration. Until recently the chemical teaching in this school was done by the second master, who had the whole of the school hours not engaged in teaching science occupied in his own form in general subjects. A public

day-school does not usually (like a science college) possess paid demonstrators and assistants ; hence, unless the teacher has a considerable amount of time not actually occupied in teaching, it is impossible for him to make and set up apparatus for experiments in a proper manner, and experiments that constantly fail are worse than none."

(ii.) The following statements deal with the difficulties that ensue from the relatively low place which is generally afforded to chemistry in the school curriculum, and the low value which is assigned to it in public examinations as compared with the value attached to other subjects. This, it is said, often leads to the restriction of chemical teaching to inferior boys, some of whom may have failed in classics and other subjects. The best boys may leave the school, having received little or no instruction in chemistry.

XXII. "One difficulty arises from the low standard of public opinion as regards science. This is chiefly due to the extraordinary and utterly unaccountable view (confined, I think, to England and America) which classical men have always had of scientific studies. In this school, owing to the exceptional liberal-mindedness of the powers that be, this evil is unknown, but in other schools where I have taught the jealousy between those who represented different kinds of study was enormous, and clever boys were therefore more attracted to literature than to science."

XXIII. "As regards the difficulties in teaching chemistry, I think perhaps the first is non-classification. The boys are sent to chemistry lectures grouped according to classics ; the result is confusion. Take the fifth form for example. It is sent into the laboratory for an hour's lecture. In that form you have some of your promising boys, also some of the weak ones, very good classics possibly, whom to teach chemistry is, you know, hopeless. But the work must be done, so you take a medium course, pitching your discourse to suit the average boy ; you must be very careful to aim low, or you will certainly hit nothing. In doing this your lecture is below the promising boys, who feel a growing contempt for you or your subject, and at the same time the lowest boys are wearied by matter which they cannot grasp."

XXIV. "Two difficulties are :—(i.) Want of sympathy with natural knowledge on the part of the majority of university men who take to school work ; (ii.) strong adverse traditions in many schools, backed up by the fashionable superstition that literary rather than scientific studies constitute the education of a gentleman."

XXV. "The difficulty is that parents do not yet recognise chemistry as a 'paying' subject, consequently their boys neglect it."

XXVI. "A serious difficulty is caused by the fact that boys may join a class in any term. This may not be a great evil in the case of languages or mathematics, but where from the very nature of the subject it is necessary, in order to understand and benefit by a lesson, that the preceding lesson should be first mastered, the case is altogether different, and it is not clear how this and the kindred difficulty of grouping in one set boys of very unequal powers and attainments can be obviated, seeing that schools are classified on other lines, generally according to proficiency in classics."

XXVII. "I believe that one of the great stumbling-blocks in the way of chemical teaching in day-schools is, that boys are often sent to the science master in classes determined by their position in classics or English subjects, so that there is no proper gradation in the teaching. This obtained here until recently, but now, by simultaneous teaching by three masters on two afternoons a week, it is possible to group the boys in the senior school according to their proficiency in science (mainly chemistry) alone. The result has been a considerable improvement in the quality of the work."

XXVIII. "The scholastic disrepute in which chemistry is held is apt to lead a head-master to devote to it the

least mentally qualified boys, who have absolutely failed on the classical side."

(iii.) It appears that the time which is usually allotted to chemistry in schools is altogether inadequate, and frequently this defect seems to constitute one of the teacher's greatest difficulties.

XXXIX. "I suppose few grammar schools give more time to chemistry than four hours a week, and so long as competitive examinations assess chemistry at one-quarter the value of mathematics, and one-eighth that of classics, more time cannot be expected. When it comes to be recognised that the mind which is scientifically trained is most likely to produce work valuable to the community, and at the same time is best suited to grapple with the practical problems of everyday life, all this will be changed."

XXX. "This school contains 500 boys. The average number of those who receive instruction in chemistry is 30, and the time allotted to the subject is three hours a week."

XXXI. "The difficulty is to make all pupils take a real interest in the work; in the short time which is allowed to the subject it is apt to become a mere collection of facts in the boy's mind. It is a curious fact that a double labour is expected from the teacher of science, namely, a general development and quickening of the reasoning faculties, and the teaching of examination-chemistry at the same time; and all this has to be done in two hours a week! Parents at any rate tacitly pay a very high compliment to the resources of science when they expect this. As a matter of fact, the unfortunate science master very naturally leaves the great work of development to the master who monopolises the remaining twenty-six hours of the week's work."

XXXII. "The time allowed to the 65 boys who learn the subject is one period a week of forty-five minutes."

XXXIII. "All the pupils who are taught chemistry—491—devote two hours per week to the subject, and 110 of these have, in addition, a weekly lesson in laboratory practice, lasting one hour and a half."

(To be continued).

NOTICES OF BOOKS.

Gas-Works Statistics, 1888. Compiled from Special Returns received from Engineers and Secretaries throughout the United Kingdom. Edited by C. W. HASTINGS. London: Hazell, Watson, and Viney.

As we have had occasion to remark on former occasions, gas-producers are more communicative than the gatherers and distributors of water. Few gas-works seem to have omitted answering the questions addressed to them as to their make. We notice that in some half-dozen towns the production and consumption of gas exactly balance each other. In two towns, thanks possibly to the depraved ingenuity of the meters, more gas has been sold than made; and Barnard Castle, though making 14,300 thousand cubic feet of gas, has been unfortunate enough to sell only 1200.

A peculiarity, for which the compiler cannot be held responsible, is that the returns are not for identical seasons. Whilst some gas-works have sent in their accounts down to the end of March in the present year, others come down only to dates in 1885, 1884, and two—Alton and Spondon—furnish information respectively only down to the middle and the end of 1882.

As regards illuminating power, Berwick still heads the English list with 30-candle power, a figure not uncommon in Scotland, where Banchory leads with a 33-candle gas. The question has been raised whether such very high illuminating powers are not uneconomical, in cold weather, when certain hydrocarbons are in danger of being condensed in the mains and service-pipes.

Water-Works Statistics, 1888. Edited by CHARLES W. HASTINGS. London: Hazell, Watson, and Viney, Limited.

THESE statistics have been greatly improved. We now find, in parallel columns opposite the names of the towns or districts, the source of supply, the character of the water, the extent of supply, the death-rate, the quantity raised per annum, and the character of the service as constant or intermittent, besides information of no sanitary moment, though interesting to investors. It is to be regretted, however, that the returns given by officials are sometimes very deficient and even unmeaning. The column "Source of Supply" is evidently intended to show the geological character of the gathering grounds, or of the strata in which the wells are sunk. But one town actually writes under this head "pumping and gravitation" (!). Fully half the towns do not give their death-rate, and on the character of the water we meet with very various information. Some towns give the hardness—permanent and temporary—of their water-supply. It is evident that, if these figures could be universally obtained, we could find a definite answer to the question as to the relative wholesomeness of hard and soft waters; but not a few towns tell us merely their water is "excellent," "very good." We need scarcely say that these shortcomings are in nowise due to any neglect on the part of Mr. Hastings, as he cannot enforce answers to his enquiries. Aylesbury and Tring still observe a solemn silence as to their water, which is the more strange as the Chiltern Hills Water Company, which supplies these towns, has no reason to be ashamed of the quality furnished.

The information concerning the adoption of the Clark process for softening chalk waters is not so full as we might wish. In one case we find it stated in a footnote that a certain water "requires to be hardened." We should venture to suggest that the average daily supply per head of the population would be a more interesting item of information than the quantity raised (or collected) per annum.

The Extra Pharmacopœia: with the Additions introduced into the British Pharmacopœia, 1885. By W. MARTINDALE, F.C.S.

Medical References, and a Therapeutic Index of Diseases and Symptoms. By W. WYNN WESTCOTT, M.B. Fifth Edition. London: H. K. Lewis.

THE present edition of the former work shows no falling off from its predecessors in point of utility. A considerable number of new remedies, natural and artificial, have been more or less engaging the notice of the medical profession, and are here duly noticed. The uses of cocaine are especially discussed at great length.

We must demur to the statement that magenta, unless specially prepared for medicinal purpose, *always* contains arsenic. Some large makers obtain this dye by Couper's process, in which arsenic is not at all employed.

Saccharine comes in for full consideration. It is admitted that its alkaline preparations have a mawkish taste, and that in the pure state a "flavour of bitter almonds is slightly developed." It is added that the taste of saccharine remains longer upon the palate than that of sugar. Probably the French experts were right in pronouncing it useful as a medicament,—*e.g.*, in diabetes,—but inadmissible as an ingredient in articles of food and drink.

Detection of Hydrogen Sulphide in Urine.—F. Müller.—The author passes through the sample a current of air which has been freed from sulphuretted hydrogen by a previous passage through potassa lye, and allows it to issue through a narrow tube, at the mouth of which is a slip of paper saturated with an alkaline solution of lead acetate, and which will turn brown if sulphuretted hydrogen is present.—*Zeitschrift. Anal. Chem.*, xxvii, Part 1.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Moniteur Scientifique, Quesneville.

Series 4, Vol. ii., July, 1888.

Summary of Improvements in Dyeing, Tissue Printing, and Bleaching during the Second Half of 1887.—Dr. Paul Julius.—The author notices in the first place artificial colours for cotton. Since it has been found that certain azo-colours dye cotton without a mordant all manufacturers seek to add to their number. The investigators follow two distinct methods: some endeavour to substitute for the bases already known as producing cotton colours, such as benzidine, tolidine, dianisidine, &c., other new amines. Others seek among the number of phenols, amines, and their sulphonic or carbonic compounds for those which have not been already claimed by prior inventors, and they thus derive new colours without scientific effort. Among the principal cotton colours lately brought out during the latter half of 1887 are the rosazurine G and R and heliotrope of the company, formerly Fr. Bayer and Co. They bear acids well. The colours produced by the Berlin Aniline Company under the names Congo brilliant G and R are also relatively fast to acids. Fr. Bayer and Co. produce a benzo-purpurine 6B. Casella and Co., of Frankfurt, have introduced a new cotton red under the name of diamine red 3B. Delta-purpurine is a mixture of the colour just named and a dye verging on Congo brilliant. Fr. Bayer and Co. and the Berlin Aniline Co. have brought out a new cotton yellow under the name of chrysamine R. The black violet of the Baden Aniline Co. behaves on the fibre in the same manner as congo and benzo-purpurine. Acids turn it to a blue-black, but do not strip it. With basic colours it plays the part of a mordant. The number of colours prepared with diamido-stilbene-disulphonic acid is still more considerable than that of the congo group. Leonhardt and Co. have thus brought out so-called Hessian yellow, violet, and purple. These colours are injured by the smallest quantity of a salt of copper, and have to be dyed in wood or tin pans. The (Berlin?) Aniline Co. has patented colours derived from stilbene and playing the double part of dyes and mordants. Brooke, Simpson, and Spiller have produced primuline yellow, which dyes cotton at once in a boiling bath, and which may be converted on the fibre by special treatment into "ingrain red" and "ingrain orange." The Berlin Aniline Co. announce that all the "congo" colours and the derivatives of stilbene fix themselves upon wool at a boil. The process is very slow, but the shades are absolutely fast to the most severe fulling. Casella and Co. also send out two fulling reds, which are not very beautiful. The Baden Aniline Co. produce rhodamine, a colour belonging to a novel group. By its basic character and its dichroism it borders on the safranines, but it is distinguished from them by the colour of its solution in monohydrated sulphuric acid, which is brown and not blue or green. J. Walder prepares a novel anthracene colour by the action of anthraquinone-disulphonic acid upon sodium nitrite. The Baden Co. sell an alizarin black which resists light better than the logwood blacks. J. R. Geigy produces two new vegetable colours, xanthaurine and anthracine. These extracts, with mordants of acetate of chrome, alumina, or salt of tin, yield all the shades from pale yellow to old gold. Zulz affirms that Indian yellow is probably a product of animal excretion.

New Analytical Methods.—We find under this head a process for the joint determination of caustic and carbonated alkali, proposed by Isbert and Venator. The sample is diluted and a few drops of an alcoholic solution of rosolic acid are added. Normal acid is then dropped

in until a distinct yellow colour appears in the cold. This point shows the saturation of the free alkali. The liquid is then kept at a boil, when the red colour returns and the acid is again dropped in until a permanent yellowness appears. The acid employed shows the quantity of alkali as carbonate.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Blown Oil.—I have been much struck at times with the indefiniteness of the information afforded by authorities on various subjects, and especially is this true of the treatment of oils. As an instance, desired to know how to prepare "blown oil," mentioned on page 129 of Mr. A. H. Allen's valuable work, but was not afforded much information on the subject. He says, "Blown oil is manufactured by blowing air through warm rape, cottonseed, or other oil. Great heat is developed, and the oil gradually increases in density and viscosity till it presents a close resemblance to castor oil." He does not give any information as to the heat to which the oil should be raised before the blowing, or how much heat would be developed, or the duration of the blowing. Brannet is less satisfactory, not mentioning the subject at all. I have found Mr. Allen's work very satisfactory in the main, but in many places it seems to be wanting in definiteness, as in the above case. What I desire now is information from any of your subscribers which will shed more light on the subject.—**WILLIAM JAMES MULLINS, Chemist.**

TO CORRESPONDENTS.

A. C.—Sodium hydrate in solution has no injurious action on iron or steel, and its use in steam boilers has been advocated by Mr. Spiller for the prevention and cure of incrustation.

Mr. R. R. Tatlock writes to say, with reference to the paragraph on p. 149 of the "Students' Number," that the firm of Messrs. Wallace, Tatlock, and Clark, of 138, Bath Street, Glasgow, no longer exists, and that the firm with which he is now connected is that of Messrs. R. R. Tatlock and Readman, City Analysts' Laboratory, 156, Bath Street, Glasgow. (See Advertisement).

UNIVERSITY COLLEGE, LIVERPOOL.

PROF. J. CAMPBELL BROWN requires an additional Assistant. Candidates must be Graduates in Science. Applications, with a detailed statement of special training in Chemistry, may be sent on or before October 16th. Salary, £100. Address, Brownlow Street, Liverpool.

2 Cast-iron Tanks, 81 ft. 6 in. diameter, 22 ft. deep.
1 " " 51 ft. " 18 ft. 7½ in. "
at £3 10s. per ton f. o. b. Rotterdam.—Apply to Old Gas Works,
Scheepstimmermanslaan, Rotterdam.

SALE of the SITE of the MARSH CHEMICAL WORKS, Llansamlet, Swansea, near the Junction Station of the Great Western and Midland Railways, from which a siding runs to the Works. Stack 100 feet high, Area of address 1 Acre, £37 10s. 6d. per foot, not over 10 years old. Works were built at an elevation of 20 feet, thus giving ample space and depth for waste. For particulars and conditions of sale address Mr. J. E. Stevens, Solicitor Swansea.

TO WHOLESALE DRUGGISTS, PERFUME AND HERB
DISTILLERS, AND OTHERS.

TO BE SOLD, with or without the Premises, the Goodwill of the old-established Business of **POTTER and MOORE**, Distillers of Essential Oils, which has been carried on at Mitcham, Surrey, for upwards of a century. For full particulars apply to **BLAKE, HADDOCK, and CARPENTER**, Auctioneers, &c., 45, High Street, Croydon.

ASSAYING.—Special Facilities are given for instruction and practice in the Assaying of Gold and all ores in the Metallurgical Laboratories of King's College, Strand, London. Persons of all ages are admitted at any time for a period of one month or upwards. Special arrangements are made for those who cannot devote their whole time to the work. For further particulars apply to Prof. Huntington.

WEGELIN AND HÜBNER, Halle-on-Saale, MACHINE WORKS AND IRON FOUNDRY.

Representatives: NICKELS & Co., 150, Holborn, London, E.C.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37,746,
with increased effect through abolishing the noxious spaces; best
Air-Pump for Compression and Evacuation; useful effect up to 90
per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment,
with Attachment for Filtration with Exclusion of Air; in Wood,
Iron, or Bronze every desired size

Experimental Filter Presses in Wood, Iron or Bronze.

Filtration Experiments, if desired, carefully conducted in
our Laboratory.

Steam Pumps & Transmission Pumps,
horizontal, vertical, mounted on column, Wall Pumps, Pumps for
Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids.
"Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or
Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids,
any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof,
i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c.
Also Small Ice Machines for Families, Laboratories,
Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure,
or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Com-
pound Steam Engines.
From 2—150 horse-power

Steam Water Pumps,

newest, most approved Construction, taking up little room, and
especially suitable for placing in Wells, with great efficiency; up
to largest sizes.

Compressors driven by Steam or Belt,
for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon,
Ether, Alcohol, Acetone, Water; in Iron or Copper. (Extraction
Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.
Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans,
and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin
Refineries, Resin Distilleries, Paraffin Works, Tar Dis-
tilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest
References for our above-named Specialities on
Application.

PETROLEUM JELLY,

EQUAL TO AND CHEAPER THAN VASELINE.

SANITARY FLUID AND SHEEP DIP,
THE CHEAPEST AND BEST DISINFECTANT.

GREASE, PITCH, ASPHALTE, AND ALL PRODUCTS OF TAR AND RESIN.

Samples and Prices on application.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1506.

ON THE ABSORPTION SPECTRUM OF OXYGEN.

By Professors LIVEING and DEWAR.

THE observations here described are the outcome of experiments which we have commenced on the spectra of gases under high pressure. The gases were contained in steel tubes, and the first difficulty to be overcome was the provision of windows capable of sustaining a pressure of 250 atmospheres. For this purpose the tubes were provided with gun-metal ends carefully fitted with curved conical bearings forced home with powerful screw caps. These gun-metal ends were perforated with conical holes, to which were fitted quartz stoppers with plain polished ends. The stoppers were 2.1 centimetres thick and of the same diameter at the smaller end. They were bedded in the openings of the gun-metal with a thin layer of wax to insure a large bearing surface, without which they are liable to fracture in the planes of greatest pressure. The tubes were likewise fitted with screw-valves near each end for the admission and escape of gas. Two steel tubes were used, each 5 c.m. in diameter, one 1.6 metre long and the other 18 metres long. The shorter tube had in it at its centre a quartz lens of rather less diameter than the tube, and of such focal length that when a light was placed 15 c.m. from one end of the tube an image of it was formed on the slit of a spectroscope at about the same distance from the other end. The longer tube had two such lenses in it, one about 30 c.m. from each end, so that when a source of light was placed in the focus of one lens a beam of parallel rays passed through the greater part of the tube and was collected upon the slit of the spectroscope by the other lens. These lenses were each held in place by three springs pressing against the walls of the tube. The soundness of the tubes and stoppers was tested by water pressure by means of a Caillietet pump, up to 260 atmospheres. The oxygen used was ordinary oxygen, previously compressed into an iron bottle. The gas was first allowed to stream through the tube, both valves being open, until all the air was expelled. The exit tube was then closed, and the pressure of the oxygen allowed to rise in the tube, and the spectrum was examined from time to time at different stages of pressure. The light employed was an arc lamp.

Using the shorter tube filled with oxygen at a pressure of 140 atmospheres, the following absorptions were visible:—

1. A narrow very black band in the extreme red, distinctly divided into two parts, well-defined on the more refrangible side, and diffuse on the less refrangible side, coinciding in position with A of the solar spectrum. We were unable to resolve this band into lines, even by the use of a large spectroscope and one of Rowland's large gratings, although the red potassium lines, produced by sprinkling a little of a potassium salt on the electrodes of the lamp, were seen through the tube sharply defined and widely divided.

2. A similar, but less strong band, also distinctly divided into two parts, but not further resolvable, in the position of B of the solar spectrum.

3. A broad dark band in the orange, diffuse on both edges, and extending from about λ 6360 to 6230, covering the place of α , which could not be detected.

4. A stronger and broader dark band in the yellow (Brewster's δ), diffuse on both edges, but rapidly coming to a maximum intensity on the less refrangible side, and extending from about λ 5815 to 5675. The maximum intensity of this absorption was at about λ 5785.

5. A faint band in the green at about λ 5350.

6. A dark band in the blue, diffuse on both edges, extending from about λ 4795 to 4750.

7. A very faint band in the indigo at about λ 4470.

When a photograph was taken with a light through the tube, all rays above λ 2665 or thereabouts appeared to have been absorbed, and the light began to diminish at about λ 2705.

When the pressure of the oxygen was further increased to 165 atmospheres the intensities of the absorption bands were increased and the diffuse edges a little widened, but no new bands were noticed. When the pressure was let down the reverse effect followed.

At 115 atmospheres the faint band in the indigo, λ 4470, was hardly traceable, and the other absorptions were weaker, and A, though weaker, was more sharply defined.

At 105 atmospheres the band in the indigo had disappeared.

At 90 atmospheres A and B were still well seen and sharp, all the bands weaker, that in the green hardly visible.

At 45 atmospheres A was still well seen, B just visible, the other absorptions very faint indeed.

At 40 atmospheres A was still well seen, B had disappeared, and of the other bands only a trace of the strongest in the yellow was left.

At 30 atmospheres A could be still seen, but the bands were all gone.

A continued to be visible when the pressure was further reduced to about 20 atmospheres. To see it easily it was necessary to use a wide slit and cut off some of the brighter part of the spectrum with a piece of cobalt-blue glass.

The radiation absorbed by the oxygen at high pressure caused an increase in the pressure in the tube, which amounted to nearly 5 atmospheres.

As these absorptions were produced by uncombined oxygen, it was a matter of interest to determine whether the compounds of oxygen would produce anything like them. Angström's observations had shown that aqueous vapour did not produce them in the visible part of the spectrum. Miller had determined that aqueous vapour absorbs very little of the ultra-violet rays. We tried, however, carbonic acid gas and nitrous oxide, both at pressures of about 50 atmospheres, but in neither case did a column of the length of our tube give any visible absorption band. A photograph showed that the nitrous oxide cut off all light above λ 2450 or thereabouts, but this is a point much higher than that at which complete absorption by oxygen begins.

These observations establish the remarkable fact that oxygen does not carry with it into its compounds its absorptive power, and that the compounds are more transparent, within the range of the radiations we have observed, than the element itself. Hartley found that oxygen, with a small percentage of ozone at atmospheric pressure in a column 36 inches long produced an absorption in the ultra-violet extending from λ 285 to 232, and that there was a feeble transmission of light above λ 232. Our photographs did not show that any light in this highest region was transmitted through the compressed oxygen.

The absorption bands we have observed appear to be identical with those observed by Olszewski to be produced by a thin layer of liquid oxygen. He describes them as extending from λ 634 to 622, from λ 581 to 573, at λ 535, and from λ 481 to 478. The band seen by us in the indigo is very faint, so that it is not surprising that he should not have noticed it. A would be rather difficult to see under the circumstances under which Olszewski worked, so that it may have been present, though unobserved (*Wied. Ann.*, xxxiii., p. 570).

Janssen says (*Comptes Rendus*, April 16, 1888) that he had observed the same bands as Olszewski, using compressed oxygen, and that the absorptions are divisible into two series:—

1. Those resolvable into lines, of which the intensity is proportional to the product of the thickness of the stratum into the pressure of the gas directly. To this series A and B belong.

2. Those not easily resolvable into lines, of which the intensities are proportional to the product of the thickness of the stratum into the square of the density. To this belong the other bands.

It is very probable that the reason why we did not succeed in resolving A or B into lines was because the lines were so much expanded, owing to the density of the gas, as to obliterate the interspaces. This is borne out by the observation that the more refrangible edge of A became more sharply defined when the pressure was reduced.

All the bands we observed, except that in the indigo, appear to be identical in position and general character with bands observed by Angström in the solar spectrum, and found by him to be persistent in time of extreme frost, when the lines due to aqueous vapour were dried out. But although the quantity of oxygen through which we observed was, even at the highest pressures employed with the shorter tube, considerably less than is contained in a vertical column of the earth's atmosphere of the same section as our tube, the bands we observed were far stronger than those in the solar spectrum. This tallies with Janssen's law above given, that the intensities of these diffuse absorptions vary as the square of the density of the absorbent gas.

We next tried the effect of the longer column in the tube 18 metres long. Filled with atmospheric air at ordinary pressure it gave no absorption which could be detected, but when oxygen at atmospheric pressure was substituted for air, A could be seen though B was not visible, nor any other absorption. As the pressure was increased first B came out, and then the band in the yellow above D. At 20 atmospheres the bands in the orange and blue were just visible. At 30 atmospheres A was very strong indeed, B strong and sharp, the bands in the orange yellow and blue were quite strong, that in green just seen, and that in the indigo doubtful. The pressure was gradually increased up to 90 atmospheres, when the quantity of oxygen in the tube was about equal to that contained in a vertical column of the earth's atmosphere of the same cross section. The increased density very much increased the intensity of all the bands, but brought out no new bands in the visible spectrum. There seemed, however, to be a general absorption at the red end, extending to about one-third of the distance between A and B, which somewhat obscured A. B remained quite sharp, the diffuse bands were somewhat expanded, and the bands in the green and indigo were well seen, though still not very dark.

Photographs showed a new band, though rather weak, just above the magnesium triplet, near L of the solar spectrum, a stronger absorption band extending from about λ 3640 to 3600, and a diffuse broad band over O. Above P there appeared to be complete absorption, as an exposure of a very sensitive plate for ten minutes brought out no impression beyond about λ 3360. Egoroff (*Comptes Rendus*, ci., p. 1144) found that traces of A remained visible when the layer of atmospheric air through which he looked was reduced to 80 metres. We were able to see A produced by a column of oxygen equivalent to 90 metres of atmospheric air.

Janssen (*Comptes Rendus*, ci., p. 650) says that in the absorption spectrum of oxygen at a pressure of 27 atmospheres in a tube 60 metres long there are rays between A and B and between B and C. Our tube, 18 metres in length, filled with oxygen at 90 atmospheres, would contain the same amount of gas as a tube of the same section 60 metres long, filled at a pressure of 27 atmospheres, but we could see no trace of the rays in question.

Observing through the tube a sheet of white paper so placed as to be strongly illuminated by the sky, the transmitted light appeared to the naked eye to have a faint blue tint, similar to that presented by liquid oxygen, and

due, no doubt, to the amount of absorption in the orange and yellow.

When some of the gas was allowed to escape, so as to reduce the pressure, the tube became almost or quite opaque. When not quite opaque the light transmitted appeared to have a greenish tint. In this case a cloud may have been formed and may have caused the opacity. When gas at high pressure was entering the tube some curious appearances presented themselves. If the gas came in slowly it appeared, on looking through the tube, as if two liquids which do not mix, one black and the other colourless, were being stirred together; and if the gas entered at all rapidly the tube became absolutely opaque. We suppose this must be due to reflexion at surfaces where there was a change of density. When the stream of entering gas was cut off the tube remained opaque for more than a minute and only gradually resumed its transparency. Precisely similar appearances could be produced by heating the tube at one or two points. When the gas was at rest in the tube the arc light seen directly through it was unbearably bright, but it was completely extinguished when the currents were set up in the tube. It is evident from this that currents of different densities in the atmosphere of a star may entirely cut off all the light coming from the interior.

It appears, too, from the strong absorption of the ultra-violet rays by oxygen that we have little chance of knowing what high ultra-violet rays are emitted by stars unless we can make our observations from points very high in our atmosphere, and unless the atmospheres of the stars contain but little free oxygen.

The whole series of observations suggest points about which interesting speculations arise. The absence in the compounds of oxygen of all traces of the absorptions produced by the element may perhaps be due to a shift of these absorptions on the scale of wave-lengths. The vibrations assumed by carbonic acid gas, for example, may be harmonically related to those of oxygen, but be higher or lower on the scale and beyond the range of our observations. The increase of the diffuse absorptions with the square of the density of the gas may be interpreted as an indication that it is only during encounters of the molecules that the corresponding vibrations are taken up. It should be observed, however, that Janssen does not, in the note above quoted, give any very definite data by which the exact truth of his law can be verified, though it seems to be established that the intensities of these absorptions increase more rapidly than the density of the gas. The distinction, too, between the bands easily resolvable into lines and those not so easily resolvable seems to be one of degree only, as we were unable to resolve A or B as given by the dense gas, and Angström has observed that the band in the yellow, Brewster's δ , in the solar spectrum was resolved into fine lines when the sun was high, but appeared as a continuous band when the sun was low. Increase of density in the gas seems to expand the bands in every case, and estimates of the intensity of A may be estimates rather of the breadth of the lines than of their absolute blackness.

ANALYSES OF TWO MONEYS.

By J. CUTHBERT WELCH, F.C.S.

I. SOME time ago several specimens of "manilla money" came into my hands, and curiosity, added to a statement I had several times heard made—that in their manufacture refuse scraps of various old metals were thrown into the melting-vessel—led me to determine the composition of some of them.

This money is made in Birmingham and I believe by several firms, and is used by the natives on the West Coast of Africa. It is of a yellowish-red to reddish-yellow, brass to bronze-like colour, and of the shape and

size given below, and weighs $2\frac{1}{16}$ ounces, avoird. Three specimens, homogeneous in appearance, gave the following results on analysis :—

	I.	II.	III.
Lead	23.92	19.54	16.81
Iron	0.82	0.31	2.15
Tin	2.70	0.04	1.56
Copper	65.48	71.84	75.62
Zinc	2.65	3.41	1.02
Antimony ..	2.01	3.56	0.35
Arsenic	2.12	1.03	2.71
	99.70	99.73	100.22

Some of the specimens were very easily broken by pressing the two ends towards each other in the hand. This appeared to be due to two causes : firstly, to imperfect casting and flaws in the metal ; and secondly, to the

presence of pieces of originally unmolten metal in the body of the coin. In three cases this particular piece was separated as completely as possible from the matrix, and analysed with the following results :—

	I.	II.	III.
Lead	30.25	4.56	22.56
Iron	4.12	2.63	1.34
Tin	0.51	—	—
Copper	64.18	89.94	74.15
Zinc	0.62	2.47	0.32
Arsenic	—	—	0.41
Aluminium ..	—	0.24	0.73
Carbon	—	—	0.24
	99.68	99.84	99.75

Nos. I. and II. seemed fairly homogeneous, but in the case of No. III. it was impossible to obtain a really fair sample, the mass having only a semi-fused appearance. The determination of the carbon, too, cannot be relied on, it probably being rather low.

A fourth specimen broke, due to the inclusion of a piece of scoriaceous material.

Thus the coins seem to be composed of a variable alloy of lead and copper with small quantities of other metals, but no aluminium ; and in those cases where fracture on pressing the ends together occurs through the presence of non-homogeneous material the composition seems very variable, and the part causing fracture has the appearance of being an imperfectly fused portion of the original mixture.

II. A coin, having at first sight the appearance of a very much worn half-sovereign, on closer inspection revealed on one side a small white surface as though an old sixpence had been gilt, but on rubbing the coin to polish

it this white surface gradually diminished and finally disappeared. It then became evident that in reality it was an alloy very similar to gold in colour that had been coated with silver and circulated in imitation of an old sixpence.

On analysis the alloy gave :—

Copper	62.583
Zinc	37.262
Iron	0.106
Lead	0.013

99.964

The Brewery, Reading.

ON THE DETERMINATION OF PHOSPHORUS IN IRON AND STEEL.

By PORTER W. SHIMER, M.E., Easton, Pa.

THE solution used in the following method for phosphorus determination is the filtrate obtained in the nitric and sulphuric acid method for the determination of silicon (*Transactions of the American Institute of Mining Engineers*, vii., 346). This filtrate, being easily and quickly obtained, and always quite free from silica, is a desirable one for phosphorus precipitation. In order, however, to get all the phosphorus in a precipitable form the solution must be made under conditions more strongly oxidising than simple solution in boiling nitric acid. In a solution thus made I have found that the presence of a moderate amount of free sulphuric acid does not prevent complete precipitation of the phosphorus.

The method in detail is as follows :—Dissolve 1 gm. of iron in 20 c.c. HNO_3 , sp. gr. 1.20. Add to the boiling solution 10 c.c. potassium permanganate solution (20 grms. to 1000 c.c. water, filtered), $2\frac{1}{2}$ c.c. at a time. After a few minutes, when the permanganate is decomposed, leaving a heavy precipitate of MnO_2 , add 5 c.c. HCl , 1.12 sp. gr. When the effervescence due to the escape of chlorine has ceased, add a mixture of 5 c.c. strong H_2SO_4 and 5 c.c. water. Remove the watch-glass and evaporate till fumes of SO_3 begin to come off. Allow to cool and add 5 c.c. HNO_3 , 1.20 sp. gr., and enough water to dissolve the residue. Boil till all iron salts are dissolved, and filter, washing with water alone. Set aside the filtrate for phosphorus determination. It need not be concentrated by evaporation when unnecessary excess of wash-water is avoided. For silicon the residue should be washed a few times with HCl and water to remove possible traces of iron, but these washings should not be added to the phosphorus solution. The latter is heated to 80°C . and 50 c.c. ammonium molybdate solution is added (5 grms. MoO_3 , 20 c.c. NH_4HO , sp. gr. 0.96, and 30 c.c. HNO_3 , sp. gr. 1.20). Heat to 60°C . till the supernatant liquid is perfectly clear. When the solution is not too dilute, precipitation is complete in less than one hour. The yellow precipitate is filtered off, washed with acid ammonium nitrate solution, dissolved in ammonia and precipitated by magnesia mixture. The ammoniacal solution is more generally colourless and clear than that obtained by the usual method. Whenever this solution is not perfectly clear and colourless, it is my custom to dissolve in HCl whatever gelatinous residue there may be upon the paper, allowing the acid solution to drop into the ammoniacal filtrate below until it becomes acid, thus throwing down the yellow precipitate. Add a slight excess of ammonia and boil for a few minutes. Filter off the precipitate, dissolve it on the paper in a few drops of HNO_3 , and add ammonium molybdate solution. Add the ammoniacal solution of the yellow precipitate thus obtained to the main solution. The latter is then precipitated with magnesia mixture in the usual manner.

When the solution of the iron is made above, no phosphorus can escape complete oxidation, for it is subjected

to the following oxidising agencies:—Solution in boiling HNO_3 , action of potassium permanganate solution, action of chlorine given off by reaction of HCl on precipitate of MnO_2 , action of chlorine given off by mixture of strong HCl and HNO_3 , evaporation and heating till fumes of SO_3 appear, solution of residue in water and HNO_3 . These agencies may also be desirable for the oxidation of silicon, for there is reason to suspect that this element is not easily oxidised in some irons.

The following are some comparative results obtained. The "standard" method is the usual one of solution in HNO_3 ; evaporation to hard dryness; solution of residue in HCl ; replacement of HCl by HNO_3 , precipitation by molybdate solution, and final precipitation by magnesia mixture.

	Standard Method. Phos. per cent.	Method above described. Phos. per cent.
A	1.75	1.74
	—	1.76
	—	1.76
B	3.623	3.639
	3.641	3.637
C	0.560	0.558
D	0.394	0.397
E	0.582	0.588
F	0.073	0.072
	—	0.074
G	0.749	0.749

In the Bessemer iron ("F") 5 grms. iron and 8 c.c. H_2SO_4 were used. Sample "B" is a white iron, containing 2.27 per cent combined carbon and 0.08 per cent graphite. In sample "G" Mr. Lee S. Clymer, Chemist of the Durham Iron Works, obtained by the usual acetate method 0.743 per cent, and, by applying the acetate method to the filtrate from the silicon as above, he obtained 0.743, 0.740 per cent phosphorus.

The exactness with which the kind and amount of free acid can be controlled in this solution for molybdate precipitation, and the comparative purity of the yellow precipitate in case of titaniferous irons, would probably make it well adapted either for weighing directly or for solution, reduction, and titration, according to the method described by F. A. Emmerton (*Transactions*, xv., 93).

N. H. Muhlenberg and Thomas M. Drown (*Transactions*, x., 85, 329) evaporate the solution of the iron in nitric and sulphuric acids to dryness and heat till SO_3 fumes cease coming off. The phosphorus results obtained in this way are accurate, but the silicon results are too high. It is unnecessary, however, to drive off dense volumes of these irritating fumes, for complete precipitation depends not upon the absence of free sulphuric acid, but upon complete oxidation of phosphorus, and of the carbon compounds resulting from solution of combined carbon in nitric acid. Moreover, a certain amount of free sulphuric acid is necessary for a good silicon determination.

It may be interesting to add the results of a few experiments with a molybdate solution containing sulphuric acid in place of nitric acid. The solution for phosphorus precipitation was made as above, with the exception that the residue on evaporation with H_2SO_4 was dissolved in water alone, instead of water and nitric acid. This solution was heated to 80°C ., and precipitated by a molybdate solution, made by dissolving 5 grms. MoO_3 in 20 c.c. NH_4HO , sp. gr. 0.96, and adding 30 c.c. dilute H_2SO_4 (1 part strong H_2SO_4 to 4 parts water). After heating for one half-hour to 60°C . precipitation was complete. The following are the results:—

	By Standard Method. Phos. per cent.	By Use of Sulphuric Molybdate Solution. Phos. per cent.
A	1.75	1.75
B	3.63	3.64

It will be noticed that in these precipitations sulphuric acid and ammonium sulphate completely take the place

of nitric acid and ammonium nitrate. Another experiment on the iron marked "B," in which, however, 25 c.c. more free sulphuric acid was present than in the above tests, gave only 3.09 per cent phosphorus, showing that a too large excess of free sulphuric acid, like too large an excess of free nitric acid, prevents complete precipitation.

MODIFIED ABSORPTION TUBES.

By JOHN TSAWOO WHITE.

I WOULD suggest a modification of the absorption tubes used in organic analysis. The accompanying illustrations of the proposed tubes require no explanation. They are for liquid absorbents. The body of the tubes may be about 10 c.m. long and $1\frac{1}{4}$ c.m. in diameter. The tubes

need not be more fragile than the ordinary ones of light blown glass. The first form is for absorbing water with strong sulphuric acid. For absorbing carbon dioxide a combination of the two forms is used. The first tube is

half filled with a solution of caustic potash of sp. gr. 1.27, and the second tube contains sulphuric acid to absorb the traces of vapour given off from the potash solution. The exit tube of the potash bulb may contain some cotton-wool.

The potash solution will absorb a little over 0.8 gm.

carbon dioxide to form the monocarbonate. If this is thought not sufficient the caustic solution, one part of caustic potash dissolved in one part of water, recommended by Löwe, may be used. A second potash bulb may be added if complication of apparatus is of no moment. The tubes are connected with rubber tubing. The pressure of gas in the tubes will aid absorption; the pressure need not be too great when working in a stream of oxygen, aided by an aspirator. The potash bulb may also be of the form given in illustration (3), a form similar to one devised by Mitscherlich. The points where the tube is contracted must not be narrowed too much, or else the solution pushed upwards may force its way out by the exit tube.

As these absorption tubes cannot be made here, I have not been able to try them; but I may claim for them simplicity of construction and light weight, and last, though not least, accuracy, as they are formed on the same principles as those now in use.

Rangoon College, August 20, 1888.

REPORT OF THE COMMITTEE*

APPOINTED FOR THE PURPOSE OF INQUIRING INTO AND REPORTING ON

THE PRESENT METHODS OF TEACHING CHEMISTRY.†

(Concluded from p. 160).

(iv.) A CONSIDERATION of these replies has fully established the important fact that the chemical instruction which is given in schools is very largely influenced and guided by the requirements of the various Examining Boards, such as those of Oxford and Cambridge and of the Science and Art Department. Abundant testimony has been received on this point, and it is frequently declared to be a great, though apparently an inevitable, evil. The quotations cited below are selected as representing schools of very different grades.

XXXIV. "The influence exerted by external examiners on the character of the teaching. This has always been to me the most subversive of good teaching, and most damaging to the character of the work. I have had a large experience in the working of the various public examinations, and I unhesitatingly say that they cripple the work of teachers, afford no safe index as to the quality of the work, and lead to a system of book-work cram which militates against anything like mental discipline and against subsequent instruction in the higher branches of the subject."

XXXV. "But all difficulties are nothing compared with those that arise from the personal peculiarities of examiners. Unless with special pupils who, having spent most of their time on chemistry, have been able to acquire some knowledge of all its branches, a teacher is never sure that he will be able to prove to an examiner that he has taught any chemistry at all."

XXXVI. "It will be seen that the examinations for which our pupils are prepared are those of the Cambridge Local, the College of Preceptors, and the Science and Art Department, and the preparation for each is so varied that it has a very bad influence."

XXXVII. "The influence of external examiners, in my opinion, is too often to encourage mere cramming to meet out-of-the-way questions."

XXXVIII. "A class was formed from the pick of the school in connection with the Science and Art Department. My salary to a certain extent depended on the

results of the May examinations. Since the number in the class had to be limited, I naturally chose only those boys who I thought would have the best chances of getting through. For a great part of the year chemistry would be treated as a by-subject, it was only for a month or so that it had its due share in the curriculum of the school, and I must conscientiously admit that during the short period before the examination I simply crammed the minds of my pupils with equations, properties, graphic formulæ, to such a degree as to ensure passing, which they all did. I was not surprised to find that in a short time all had been forgotten. This system is adopted at many places."

XXXIX. "The teaching of chemistry here is entirely regulated by the Science and Art Department, for the simple reason that it would not exist as a class subject without the pecuniary aid rendered by the Department. I believe some really good work is being done; but the teacher is very much of a machine, and however conscientious he may be, he must primarily, under the circumstances, teach for examination, and at times neglect what would be useful to his pupils because it would not be useful for examination."

XL. "In this school chemistry is optional, and the primary object of its existence is the advantage of those boys who are going in for examinations in which it will prove useful."

XLI. "There is great variation in the standards and methods of various examinations. Three things are specially to be complained of:—(a) the bookish nature of some examination papers; (b) estimation of the value of answers by comparison with text-books by inferior men, not always the authors of the papers or themselves real chemists; (c) want of judgment in setting papers, arising often from ignorance at first hand of the conditions of school work."

XLII. "With respect to examinations, I do object to men examining boys under sixteen who have never taught them, and who, therefore, do not understand that the work of such students must differ not only in quantity, but also in quality from that of older pupils."

XLIII. "I believe that 90 per cent of those who are now taught chemistry in this country are taught with the view of passing one or other of the examinations held on the subject. Further, I believe that most of the difficulties of teaching chemistry are difficulties of teaching it so as to comply with the requirements of examinations. Some one has said that in the regulations of the Science and Art Department so much is required to be known that there is no time for anything to be done, which is an exaggeration of what I mean. With ordinary teachers one thing is necessary—their pupils must pass. When that is secured they may indulge in such novelties of method and procedure as they like, but not until then. It would avail me nothing to say that my instructions were faulty, that I knew and followed a more excellent way."

XLIV. "As to the influence of examiners. In my own teaching it has been for the last few years *nil*. I have given up trying to fit the chemical instruction to the doubtful requirements of examination; to do so would take the vitality out of one's teaching and contract it."

XLV. "With regard to the influence of external examiners on the teaching, there is no doubt that this is very great, and that the character of the teaching in our schools must depend, in these high-pressure examination-days, on the requirements of the examiners."

XLVI. "We have subjected our boys to two examining bodies—the Science and Art Department and the University Board. In successive years the boys from the same teaching universally succeeded under the former and almost universally failed under the latter."

XLVII. "The examinations have been chiefly those held in connection with the Science and Art Department, South Kensington. These examinations have been for some years back highly satisfactory, and no undue prominence has been given to any one branch of chemical

McLeod, Prof. Meldola, Mr. Pattison Muir, Dr. W. J. Russell, Mr. W. A. Shenstone, Prof. Smithells, and Mr. Stallard. Drawn up by Prof. Dunstan.

† Read at the British Association, Bath Meeting, Section B.

science. They certainly do exert an influence on the character of the teaching, but it is a restraining and beneficial influence."

XLVIII. "The influence exerted by external examiners on the teaching is decidedly beneficial *when the examiners are experienced men.*"

XLIX. "The influence exerted by external examiners on the character of the teaching is practically *nil*. They send their questions and substances, examine the results, and write their reports, and, with rare exceptions, never make a suggestion as to how the teaching may be improved or better results obtained.

(v.) The absence of good text-books suitable for use in schools is frequently stated to be a source of difficulty.

L. "One of the chief difficulties in class teaching is the want of a suitable text-book, more especially when preparation is an important factor. A text-book should, without any great amplification on the part of the teacher, make itself intelligible to the boy on reading it for the first time, and it should not be overlaid with facts."

LI. "We want a good school text-book. Existing books entirely lack connection in their various parts, and are generally made up of a series of more or less isolated facts grouped loosely under various heads. They are also too diffuse and wordy, and, therefore, very unsuited to a boy with but a limited time to prepare his lessons."

LII. "An additional difficulty is found in the absence of a satisfactory text-book, notwithstanding the multitude already extant, and this difficulty is not diminished by the consideration that, as a rule, the science master is required to devote a great portion of his time to teaching other subjects. According to my idea, the kind of book required is one that recognises the close connection between the lecture work and the practical work of the pupil; in fact, a book something after the plan of Huxley and Martin's 'Biology.'

LIII. "The greatest difficulty we meet in teaching chemistry is the want of a suitable text-book on which all our lecturers can base their teaching. Boys sometimes get different definitions of the same term, and a master does not know exactly how much boys have learnt in another class."

LIV. "Text-books are another difficulty. I have never found one yet that I liked to put into the hands of boys, for I have generally found that they are too elaborate and complete, using, sometimes, language which the ordinary schoolboy does not understand, and describing here and there experiments which he certainly cannot grasp. I have not found a book which I could put between the 'Chemistry Primer' (which, with the 'Physics Primer,' is always my preliminary course) and such a volume as Thorpe's or Roscoe's; these contain a great deal of matter too difficult and minutely exact for class work."

LV. "Further, there is the eternal text-book difficulty. A book at once clear, brief, and accurate is a desideratum."

(vi.) Some head-masters complain that they are unable to obtain properly qualified teachers of chemistry.

LVI. "Difficulties arise from the circumstance that there stands before the class a chemist who is not a teacher, or a teacher who is not a chemist."

LVII. "The scholastic dispute in which the subject is held is apt to affect the teacher. It is much easier to obtain a well-qualified teacher of classics than an equally well-qualified one of natural science."

LVIII. "Our two great difficulties here are:—(1) To get men, for anything we can offer, who are at once chemists and teachers. Mere chemists are of no use from a pedagogic point of view, and even they would be hard to get. I am convinced that a *teacher* who had a strong grasp of the principles of the science could, and would, make it an eminently valuable means of mental training. (2) The entire non-recognition of chemistry by the two universities in the earlier stages of their arts courses."

3. "The Methods which, in your Opinion, are most likely to render the Teaching effective as a Mental Discipline, and as a Preparation for Subsequent Instruction in the Higher Branches of the Science or in Applied Chemistry."

A great deal has been written in reply to the question as to the methods which ought to be followed in teaching elementary chemistry.

It is clear that the older plans of teaching, which are still largely used, are felt to be partly unsatisfactory, and that by modifying them chemistry might be made much more valuable as a mental discipline for boys. In particular protest is made against the undue proportion of time which is frequently assigned to qualitative analysis; indeed, the majority of teachers do not consider this to be the most valuable part of the subject. Others hold that it presents many advantages, and is, on the whole, the best adapted to school work, especially when instruction has to be given to large classes of boys. But while most teachers strongly deprecate a rigid adherence to the present system, and a few are able to point out the general lines on which the teaching might be more usefully conducted, it is evident that very few, if any, have yet put into operation a re-modelled system of instruction. In fact, it appears that teachers stand very much in need of advice and assistance in preparing a modified scheme of teaching suitable for general adoption in schools. It has several times been suggested that this Committee might be able to render important help in this direction.

The following quotations are typical of many of the replies which have been made. They are written by the head-masters or science masters of both large and small schools, and are here reproduced, not only because they allude to some of the principal defects of the present methods, but also on account of suggestions they contain which seem likely to be valuable to those who are anxious to make chemical teaching more effective than it is at present.

LIX. "The teaching should be experimental in all cases. The experiments need not be numerous, but apposite, and the utmost got out of them, both directly and indirectly. I find, for example, that I can get a good hour's work out of boys in the lower forms with such subjects as the separation of sand from a solution of salt, the action of water on lime, or the action of nitric acid on copper. I find that the same plan of limiting the attention to one or two important points is also most effective in the upper forms when the exigencies of examination-work admit of this kind of treatment. Notes of lessons should be relied on rather than text-books. I find, for example, that the ground covered at previous lessons is always known, but that I get next to nothing out of a set lesson from a book. This will be sure to follow from an experimental method of treatment. Above all, I would suggest the entire re-modelling of all school examinations, and the placing them in the hands of men who have had experience in teaching, and know, therefore, what to expect of boys, rather than in those of men fresh from the 'schools,' and with only the experience of university teaching. I should also like to see the range limited and the examination papers graded. The extent of the ground covered by the Local Examination papers of the universities is too great for such schools as this, though Oxford has recently much curtailed them.

"I am led to hope that your Committee may see its way to step in and produce something like uniformity and system. Would it not be possible to draw out a scheme of teaching divided into 'grades,' and suited to a progressive course, as also to issue yearly sets of examination papers adapted to these different grades? I sincerely trust that this may be one of the results of your inquiry, for I feel sure that examination by so high an authority will have a most beneficial effect on science teaching, and have a value in the hands of examiners impossible under any of the present systems."

LX. "It is, in my opinion, no use crying out against the system of examinations in this country. For years to come the nation will go on demanding results and getting them. Can those results be made more worth having? I believe they can. It lies entirely within the power of the eminent and working chemists of the country to effect great and useful reforms almost at once. It should be acknowledged that the present requirements are obsolete. Looking at the enormous and ever-increasing number of important and interesting facts, has not the time come when chemistry should be taught to beginners as biology is taught? Instead of reading about hundreds of plants and animals, a student becomes practically acquainted with about a dozen of each at first hand. Why should not a similar plan be followed in chemistry? Why should not a thorough study of chlorine include all that an elementary pupil needs to know about the halogens? The principal member of each group of the non-metallic elements might be selected for special study. As to the metals, half-a-dozen, which might be varied from year to year, if really mastered, would be much better than the knowledge which is required of them under the present system. Room would thus be found for a few organic compounds. It is pure pedantry to maintain any longer the arbitrary distinction of inorganic and organic chemistry in a first and general course. As to analysis, I think the present comparatively complete course should give place to a sound knowledge of the separation of some half-dozen substances, and the time thus saved could be devoted to easy exercises in quantitative analysis. There can be no doubt that quantitative analysis is within the reach of any student who can perform a good qualitative analysis. What I have proposed amounts to re-writing a syllabus for a first or general course of chemistry, on the basis of selecting a few typical substances and making a more or less complete study of them, and, with regard to analysis, to restrict the substances to be studied, but to require the elements of gravimetric and volumetric determinations."

LXI. "To render the teaching of chemistry of educational value it must be made inductive, and not chiefly and largely deductive. The guiding motto should be 'Prove all things.' Experiments should be made with as simple apparatus as will secure the desired result. In the earlier lessons avoid all definitions, all hypotheses of atoms and molecules, of atomic weight, and of 'bonds,' but early establish the constancy of composition of compounds and the equivalent weights of certain elements in combining with or displacing one another. I should like to see some encouragement given to the historical aspects of chemistry. I have found that explanations of when and how the chief elements, acids, and alkalies came to be known add much to an intelligent interest in the subject."

LXII. "It has always appeared desirable that a boy should approach chemistry in the same way that all the founders and builders-up of the science have done,—viz., not by first reading a printed account of facts and then verifying them or seeing them verified, but by studying the different forms of matter as substances hitherto unknown, the properties of which have to be investigated for the first time and compared with those of other substances. With this view the experiments shown are considered as questions put to Nature, the answers to which are as little known to the lecturer as to the learners. No predictions are made as to the results, although boys are not unfrequently asked what, arguing from experiments previously shown or the properties of analogous substances previously examined, may be expected to occur. All apparatus used is described, the reasons for any special arrangement of it being explained fully. Elaborate forms of apparatus with a profusion of drying tubes, Woulf's bottles, fantastically bent leading-tubes are avoided as far as possible, their tendency being to draw off attention from the main point of the experiment. The arithmetical side of chemistry is not very much enlarged upon; it seems hardly desirable that boys should look upon experiments as pegs on which numerical problems are to be

hung. Too much time may easily be spent in elaborate calculations on the quantity of zinc required to obtain enough hydrogen to decompose the nitrogen monoxide produced from 10 grms. of ammonium nitrate. Innumerable examples, however, illustrative of important laws, such as those of Gay-Lussac and Avogadro, and of calculations actually required in quantitative work, are frequently set generally at the beginning of each lecture, in reference to some point explained in the preceding one. No symbols, formulæ, or equations are used at first, not, in fact, until the properties of three or four elements, and of some of their compounds, have been studied and the laws of chemical combination deduced from them. Then, and not till then, it is thought that a learner can appreciate the value of Dalton's atomic theory in accounting for the facts he has observed, and can see the advantage of a system of chemical shorthand, and use it with intelligence and discrimination."

LXIII. "The method, in my opinion, most likely to render the teaching effective as a mental discipline is mercilessly to sweep off a large proportion of the facts at present dealt with, to confine the attention of the pupil to those that for various reasons are the most important, and to use them always as illustrations of general laws. For this purpose there must be agreement among teachers and examiners. I do not think it beyond the scope of your inquiry to suggest that, to make chemistry or any natural science do all that it can do towards mental discipline, there must be an attempt to use it as a means of destroying the contempt which familiarity breeds in us all towards common things. Unless you can call forth the interest of your pupil, his admiration, even his reverential awe towards the mystery of Nature, you have perhaps done more harm than good."

LXIV. "Eternal analyses of simple salts and mixtures such as are required by examinations of the present day weary and worry the student, waste his valuable time, and throw away labour which in nearly every individual case would be most profitably spent in carefully studying and testing some important laws or principles of chemistry, and which would make the student's knowledge of the subject thorough and personal. Chemistry is essentially an experimental science. The great value of the study of the whole subject lies in the practical work done and in the method of building the theoretical structure on the practical knowledge. It is therefore absolutely necessary to have a thoroughly good laboratory with a lecture-room attached, so that collective and individual work may be carried on with equal facility. At the present time, in our schools and colleges there is too much working for examinations, and the requirements to pass such examinations are as narrow as paper legislation can make them. The student is for ever testing mixtures or performing some exceedingly simple gravimetric analyses. He is tied down, has his knowledge fettered instead of having it expanded, and never reaches the more advanced and useful principles of chemical science, which he can only dream of from the hearsay of his text-book."

LXV. "There is no scale of value of the different parts of chemistry; there is no recognised system as to which should be taught first. I have known boys obtain scholarships simply because their teacher had been recently a pupil of their examiner and knew the kind of questions he was likely to set. The ordinary text-books, lectures, and practical work do but little for even the hardest worker. We want an authorised code of work issued by a consensus of the highest authorities."

LXVI. "I object strongly to boys in a laboratory being allowed to mix different solutions in test-tubes, day after day, to find out whether precipitates are formed or not. I have a high opinion of the advantages derivable from the teaching of chemistry when none of the harder parts are shirked, as a valuable mental discipline, and as giving, with drawing, the best means of teaching an ordinary boy the use of his hands as well as his head."

LXVII. "The result of the absence of practice in

quantitative experiments is to create an unnatural breach in the minds of pupils between the actual phenomena of chemical action and the theories by which such phenomena are to be explained. It might be found possible to treat the subject more logically if some attempt were made to teach the facts in a more natural order. The historical sequence by which the science has attained its present proportions might form the basis of a rational arrangement of the parts of the subject. In this way, by placing the pupils in the attitude of mind of original discoverers, the logical necessity of theories to account for the facts would give them more real meaning and interest. I am not acquainted with a text-book suitable for school use in which such an order is followed."

LXVIII. "Boys have been lectured to as if they were students, thereby producing a condition of things described by some writer as the perfect paradise of a boys' school, where the masters learnt the lessons and the boys heard them. Chemistry should be taught as everything else is taught—by making the boys do the work themselves; and the lesson should be a system of question and answer."

LXIX. "The calculation of chemical quantities, involving atomic weights, ought to come quite late in the course, so that the atomic theory is kept in the background at first. The pupil should make several experiments on the diffusion of gases and liquids which will lead up to the idea of molecules. I must say that I think that 'equivalents' should be used for some time before any reference is made to atomic weights. As to cramming a boy in the methods of writing equations, and finding how much sulphuric acid and zinc will make so much hydrogen, I can only say that, as the boy never attempts to carry it out in practice, and that if he did he would find his calculations all wrong as compared with his results, he had better leave them until late in his course, for their symbolic value and, in many cases, real worthlessness can only be estimated by a worker in quantitative analysis. I think a boy's practical work should undergo great alteration. At present he is examined in 'simple salts,' so of course he is prepared for that by a system of 'test-tubing' which teaches him very little. He ought to start as far as possible with elements which he knows, such as sulphur and iron, and he should prepare certain compounds which contain them. He should then study the action of metals on acids, and the salts formed; cases of oxidation and reduction; preparation and properties of gaseous elements and compounds."

LXX. "In order that chemistry may be a useful subject for the education of boys, it seems to me necessary that it should be taught from experiments involving measurements. Other experiments may be amusing, but do not appear to afford food for severe or productive thought. It seems to be now generally admitted that boys should be led as far as possible to make inferences from chemical experiments for themselves. If they are to be taught the principal facts of chemistry in this way, it follows that the experiments must be of the former nature. It seems to be an evil that so much importance is attached in many examinations to qualitative analysis, which appears, from an educational point of view, to be one of the least valuable parts of the subject. The result is that teachers are compelled to spend the time given to laboratory work on this, to the detriment of experiments of a more instructive kind."

LXXI. "For beginners, the illustrated lecture, well supplemented by periodical questioning, examination of note-books, &c., seems the only feasible way of teaching large classes of, say, thirty or forty. When the class is very small the lecture can be largely replaced by laboratory work, in which the experiments are performed by each individual student. This seems to me the best method; but my experience is that it is impossible to satisfactorily conduct large classes of young boys in the laboratory, except in such simple experiments as the action of metals on acids, which can be done with a few test-tubes and

other very simple and inexpensive apparatus, the breakages being too serious in an ordinary school if it is attempted to go through the preparation of all the commoner gases with a large class of beginners in laboratories as they are usually arranged. I think more satisfactory results might be obtained with such classes if a part of the laboratory were specially arranged for the purpose, a bench (with only a few necessary reagents) in the form of a semi-circle being used, the students facing the teacher, who would stand inside the semi-circle. In such a class the students would all perform the same experiment after being shown it by the teacher. With rather more advanced students I think the separate system is better, all students not working at the same experiment, as this obviates the necessity of providing a large number of pieces of apparatus of the same kind, and allows a quicker student to make more rapid progress. I think it is very important that quantitative experiments should be made as early as possible; but here again my experience is that young beginners cannot be trusted with balances sufficiently delicate to be of much value. The stereotyped 'test-tubing' course examination of simple salts and mixtures is certainly a very inadequate laboratory course taken by itself; but it has, I believe, its advantages for school purposes in teaching care, order, and cleanliness, and it serves well for the middle classes of the school if properly supplemented by class-teaching, in which the chemical actions concerned in the testing are carefully considered."

LXXII. "Chemistry cannot properly be taught apart from Physics; there is a physical side to every chemical phenomenon. Lecture work should precede laboratory work, and continue *pari passu* with it. Analysis rationally (not mechanically) taught is an excellent mental training. The two should be closely correlated; exercises should be given in the laboratory preparatory to or suggested by the subjects treated in the lectures, and facts learnt in the laboratory should be turned to account in the lectures. The teacher must not be trammelled by text-books: these must be his instruments, not his masters. Quantitative treatment of subjects in the lectures should be introduced as far as possible from the first, and as pupils advance they should be trained individually in the use of the balance. Numerical exercises based on (not as a substitute for) lecture demonstration help to give fixity and precision to ideas. Pupils should be trained to think out in their note-books the connection between experimental demonstration and theory, and not have notes dictated to them to be committed to memory. Their knowledge should be tested by frequent short examination papers."

LXXIII. "With regard to the practical work in the laboratory, the value of which cannot be over-estimated as a means of bringing a boy into real touch with his book-work and developing in him those valuable qualities of patience, accurate observation, and powers of deduction, so especially necessary to the student of science, analyses of complicated mixtures not found anywhere in the universe are no longer now considered as the object to be aimed at. But there is still too much tendency to regard mere analysis as the aim and object of laboratory work. Rather should a boy be introduced to a progressive course of work which illustrates the more important principles of chemistry, and so enable him to test the truth of these for himself. Here especially a good text-book of practical work is required, as a busy teacher finds it so difficult to get time to devise as well as supervise. Such a course of work must necessarily be limited in many schools owing to the want of sufficient apparatus or the short hours of work. But still something may be done in this direction, and the mental training will not only be of infinitely more value to the special student, but also to the ordinary boy, who will not be much the wiser for having gone through a course of simple and complex analysis only. I think your Committee might do much towards smoothing the path of teachers by drawing up a memorandum addressed to the head-masters of schools suggesting points for their

consideration, and asking them to meet the Committee's views on the subject as far as lies in their power."

The Committee feel that these reports have put them into possession of the actual facts connected with the teaching of chemistry in schools, and have made it clear that something should be done in the direction of promoting a more uniform and satisfactory treatment of the subject. The Committee think that some suggestions might now be made as to the method of teaching chemistry which should be followed in schools. If this can be done it will certainly confer a great benefit on both teachers and examiners, and will be likely to lead to a more emphatic recognition of the merits of the science as an instrument of elementary education. The Committee accordingly ask for re-appointment.

NOTICES OF BOOKS.

Nineteenth Report of the State Board of Health of Massachusetts. Boston: Wright and Porter.

We find here some very interesting matter bearing upon the sewage question, which is by no means as near solution or as unimportant as certain sanitarians now wish us to believe.

We see it mentioned that "the Merrimack is a good instance of the ability of a large river to receive much polluting material in the form of sewage and manufacturing refuse without becoming seriously polluted. It has, in this respect, not only the advantage of large volume, but it is unusually well aerated by agitation in rapids, dams, and water-wheels, which, without doubt, have some influence in counteracting the influence of the organic matter."

The purification of sewage by applying it to land is next considered, the conclusion reached that, "desirable as the use of sewage in irrigation is, we cannot depend upon irrigation alone, in the more thickly settled parts of the State, for preventing the pollution of streams." Yet we should conclude that in America irrigation would act more advantageously than in the moister climate of Britain.

The author, with Schloesing, Warrington, and Frankland, ascribes the decomposition of the nitrogenous organic matter in soils to the presence of nitrifying organisms, and infers that filter-beds, of proper material, can purify ten to twelve times as much sewage per acre as can be applied to our farm-lands in irrigation.

Some very interesting experiments have been conducted at Lawrence. The respective mediums used were coarse clean mortar-sand, fine white sand, peat, river-silt, garden soil, soil superimposed upon sandy loam, sand and gravel, and, lastly, compact clay, sand, and gravel covered with garden soil. Peat is found "of little value as a filtering material," the organic matter being "more than doubled." Coarse sand, on the contrary, reduced the organic matter to one-half, the free ammonia and the albumenoid ammonia each to one-fourth, and the nitrates to three-fourths of the amounts in the applied water.

We are here compelled to ask, What has become of the albumenoid ammonia if it reappears neither as free ammonia nor as nitrates? With fine sand we have also a simultaneous reduction of organic matter, of free ammonia, albumenoid ammonia, and nitrates.

The number of bacteria found in 1 c.c. of the sewage filtered was 193,000. In the effluent from the fine sand there were, on January 3rd, 6680; and on January 5th over 10,000. Some of the species in the effluent were identical with those in the sewage.

We may remark that, had these experiments been performed in summer, the results, from a bacteriological point of view, would have been more conclusive.

The Gas and Water Companies' Directory, 1888. Edited by C. W. HASTINGS. London: Hazell, Watson, and Viney.

This useful compilation addresses itself not to sanitary authorities, medical officers of health, &c., but to shareholders, debenture-holders, and to all who may have commercial relations with the companies or the bodies supplying gas or water.

The work shows, in parallel columns, the date of formation of the undertaking, date of special act (if any), total share capital paid up, dividends, loan capital; names of chairman, engineer, or manager, secretary, lessee, owner, or corporation; population, distance from London, and means of access.

The returns from gas undertakings are here more numerous than those from water-works.

CORRESPONDENCE.

IMPROVED WASH-BOTTLE.

To the Editor of the Chemical News.

SIR,—I have used an improved wash-bottle which I think will be found useful to analytical chemists and others for washing precipitates, &c.

The annexed drawing is almost self-explanatory. After blowing with the mouth as usual until a good pressure has been obtained within the flask, the india-rubber tube

may be squeezed by the thumb against the neck, and then the mouth may be removed, but the water will continue to stream out of the jet. The tube B may be tied to the flask by string, and the neck of the flask wrapped with string or other bad conductor of heat.

When the bottle needs re-filling the india-rubber tubing, A, will stretch sufficiently to allow the withdrawal of the cork.—I am, &c.,

GEORGE W. SLATTER,
Assoc. R.S.C.I., F.I.C., F.C.S.

ANALYSIS OF FERTILISERS.

To the Editor of the Chemical News.

SIR,—In the 1886 edition of Mr. Crookes's "Select Methods in Chemical Analysis" (p. 500) attention has been called to the fact of some analysts, in their examination of fertilisers, neglecting the rendering insoluble of the whole of the silica by bringing the acid solution of the phosphate to complete dryness prior to the separation of the lime; in consequence of which the siliceous matters other than actual sand, which are soluble in acids, are afterwards precipitated with the phosphoric acid and weighed as pyrophosphate of magnesia, thus yielding erroneously high results. Experimental evidence rendered by Mr. T. R. Ogilvie is given in support of the degree of error introduced, and as a result of his experiments it is shown that in some cases it amounts to a representation of 5 to 6 per cent more phosphate than the fertiliser contains.

Notwithstanding the publication of these facts it is much to be regretted that this erroneous system continues to prevail, to the detriment of those chemists carrying out the orthodox mode of complete separation. It is impossible for any chemist engaged in the analysis of fertilisers to thus carry out the letter of the chemical law without discovering the analysts alluded to in the handbook in consequence of the contradiction in results. I have before me the analysis of a fertiliser made by an eminent analyst in London in which he returned the total phosphates at 29.93, a result obtainable on neglecting the process described. The sample in question contained 25.40 per cent of actual phosphate of lime, but gave me by the co-precipitation of the silicates soluble in acid a result at 30.02.

The errors resulting from the non-separation of the whole of the siliceous matters—present in greater or less degree in all fertilisers—are not simply confined to the estimation of the total phosphoric acid, and appearing under the statement of insoluble phosphates, but they are likewise inherent in the determination of the phosphates rendered soluble. I have, during the present season, made several experiments on the determination of the soluble phosphoric acid in mineral superphosphates, with a view to ascertaining the degree of error occasioned by siliceous matters coming into solution with the acid phosphate of lime. The following few examples will serve for illustration, the lower percentages being the actual amount of phosphate of lime rendered soluble, present in each sample, the higher ones showing the erroneous results obtainable on neglecting to bring the water solution of the phosphate (with certain precautions) to complete dryness prior to the separation of the lime:—

No. 1. 24.04—25.01.	No. 3. 26.81—28.49.
No. 2. 24.80—27.36.	No. 4. 26.40—29.04.

As the erroneously high results have been issued by some chemists in their analyses of these phosphates by the magnesia method, it would appear as though they were under the delusion that acid phosphate of lime is the only substance dissolved in making up the water solution of the phosphate.—I am, &c.,

ALFRED FIRBY,

Analyst for the Tadcaster Chamber of
Agriculture, &c., &c.

Laboratory, 98, Albion St.,
Leeds, Sept. 28, 1888.

BLOWN OUT.

To the Editor of the Chemical News.

SIR,—Mr. Mullins seems to misunderstand the object of the work of mine from which he quotes. The book in question is entitled "Commercial Organic Analysis," and many chemists hold the opinion that it would have been better to have confined the subject-matter strictly to analytical methods, and left the composition and properties of the bodies treated of to take care of themselves. I

have habitually restricted the description of manufacturing operations to mere outlines, or have relegated fuller descriptions to footnotes. To have given the working details of manufacturing operations would have required much space, and would have been of little use in many cases without drawings of the apparatus used. Such a course would have converted the book into one on manufacturing chemistry instead of chemical analysis, and would have still further delayed the completion of the work.—I am, &c.,

ALFRED H. ALLEN.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 9, August 27, 1888.

This number contains no chemical memoirs.

No. 10, September 3, 1888.

In What Stage of Oxidation do Chrome and Manganese Exist in their Fluorescent Compounds?—Lecoq de Boisbaudran.—The author holds that rose-coloured fluorescent chromiferous alumina, prepared in hydrogen, cannot easily contain chromium in a stage of oxidation higher than Cr_2O_3 .

Revue Universelle des Mines et de la Metallurgie.

March, 1888.

This issue contains no chemical matter except a notice of certain Australian minerals, from the CHEMICAL NEWS, and an abridged account of Professor L. de Koninck's process for the determination of carbon in commercial irons. The ordinary method consists in the separation of the carbon by means of a solution of cupro-ammonium chloride, and a subsequent combustion of the carbon by the moist way. Without great care is taken in washing the carbonaceous residue, chlorine may be evolved along with carbonic acid. To avoid this error Professor de Koninck introduces into the combustion flask a little silver sulphate.

April, 1888.

Manganese-Steel.—This paper is chiefly devoted to the physical, and especially the mechanical properties of this alloy. The writer, with Bresson, now considers that steel should in future be defined, not as an iron carbide, but as "a peculiar state of iron, produced by the union of this metal with bodies whose nature may vary, such as carbon, manganese, chromium, tungsten, and silicon.

Qualitative Separation of Gold and Platinum from Arsenic, Antimony, and Tin.—Prof. de Koninck and Dr. A. Lecrenier.—The precipitate of sulphides, dry or moist, is heated in a current of hydrochloric acid gas, produced by the action of sulphuric acid upon ammonium chloride in fragments in an apparatus described by one of the authors in the *Zeitschrift für Analytische Chemie* for 1880. The antimony and tin are quickly volatilised as chlorides, the arsenic sulphide is expelled unchanged, whilst gold and platinum remain behind.

Determination of Sodium Chloride in the Alkaline Waters of Coal Mines.—Prof. de Koninck.—The water to be examined is introduced into a flask marked at 200 c.c. and at 220 c.c. The water must extend to the first mark, and a solution of calcium nitrate is introduced up to the second mark. This solution must be of such a strength that the salt may be in excess with reference to the sodium carbonate. It is shaken up for a few moments

and filtered through a dry filter, 110 c.c. of the filtrate being collected. The calcium carbonate, in its precipitation, carries down the colouring-matters so that the filtrate is perfectly limpid and neutral. Of course the chloride can now be determined by means of a standard solution of silver nitrate, using potassium chromate as indicator. The result, multiplied by 10, shows the weight of sodium chloride contained in a litre of the water.

Determination of Manganese in Slightly Manganiferous Cast-Iron.—C. Reinhardt.—From 3 to 4 grms. of the metal are treated in a covered vessel with 30 to 40 c.c. of hydrochloric acid of sp. gr. 1.19. A little potassium chlorate is added. The reaction is at first let go on in the cold, and heat is then applied until the solution is completed. The liquid is then evaporated down to 15 to 20 c.c., an equal volume of cold water is added, and the whole is filtered. The filtrate is collected in a flask marked at 500 c.c.; 5 c.c. of nitric acid at sp. gr. 1.4 are added per grm. of metal, and the mixture is boiled until it takes a decided yellow colour. The solution is cooled; milk of oxide of zinc is added until the iron is precipitated, the flask is filled up to the mark, and the liquid is filtered through a dry filter. 250 c.c. of the filtrate are collected and the manganese is precipitated as dioxide with the aid of heat by means of sodium acetate, bromine, and zinc oxide. The precipitate is collected upon a filter, washed, dissolved in dilute sulphuric acid containing a known quantity of oxalic acid, the excess of which is finally determined by means of a standard solution of permanganate.

Now ready, Crown 8vo., cloth, 5s.

THE ANALYSTS' LABORATORY COMPANION. By ALFRED E. JOHNSON, Assoc. R.C.Sc.I., F.I.C., F.C.S., Royal Prizeman in Chemistry, Physics, and Mathematics of the Royal College of Science for Ireland.

London: J. and A. CHURCHILL, 11, New Burlington Street.

ASSAYING.—Special Facilities are given for Instruction and practice in the Assaying of Gold and all other ores in the Metallurgical Laboratories of KING'S COLLEGE, Strand, London. Persons of all ages are admitted at any time for a period of one month or upwards. Special arrangements are made for those who cannot devote their whole time to the work. The Laboratory, besides being open every day, is open from 7 to 9 on Friday evenings.—For further particulars apply to Prof. HUNTINGTON.

Analytical Chemist, late pupil of A. Smetham, Esq., Liverpool, Assistant with F. Sutton, Esq., Norwich, wants situation in Chemical Works.—Address, "Rekrah," 26, Harford Street, Norwich.

Required, in a London Assay Office, a Pupil Assistant. Small Salary offered.—Address, "Litharge," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, a Well-educated and Intelligent Youth, about 18, with a knowledge of the Chemical Apparatus Trade.—Apply, H 500, CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, by a large Provincial Gas Company, a thoroughly competent Foreman, to take charge, under the Engineer, of Sulphuric Acid and Sulphate of Ammonia Works. Must have had experience in making acid from spent oxide of iron, and be capable of controlling workmen. Good house, with coals and gas provided.—Apply, stating experience, references, and wages required, to S., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

PARTNERSHIP.—A Young Gentleman with a thorough knowledge of Technical Chemistry wishes to meet with an Appointment with a view to Partnership in some manufacture where such knowledge might be profitably employed. Has had experience in Works, is a good Accountant, and could invest some Capital.—Address, Box 777, CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

SALE of the SITE of the MARSH CHEMICAL WORKS, Liamsamlet, Swansea, near the Junction Station of the Great Western and Midland Railways, from which a siding runs to the Works. Stack 100 feet high. Area of land five acres. Rent £37 10s. Unexpired term 67 years. The Works were built at an elevation of 20 feet, thus giving ample space and depth for waste. For particulars and conditions of sale address Mr. J. E. Stevens, Solicitor Swansea.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1507.

ON THE INFLUENCE OF SULPHUR UPON EGGERTZ'S CARBON COLOUR-TEST.

By T. W. HOGG.

It is now pretty well known that Prof. Eggertz's simple process for the colorimetric determination of carbon in steel is open to many sources of error.

In the first place the colour intensity of a solution of steel in nitric acid of 1·2 sp. gr. does not depend entirely upon the quantity of carbon which may be present, but also so much upon its condition that in some special cases the results become quite misleading. Again, the colouring-matter which gives to the solution its peculiar tint is so extremely sensitive to external influences that serious errors occasionally arise from the neglect of certain necessary precautions. The other elements usually present in steel are generally supposed to be without any influence upon the colour-test, and, so far as I have been able to find, the only experiments bearing upon this point have been conducted by Prof. Eggertz himself, and an account of them may be found in the *CHEMICAL NEWS*, vol. xlv., p. 173.

Amongst the substances examined is the element sulphur, and in order to ascertain the influence of it, 0·001 grm. in the form of magnesium sulphate, was added to 0·1 grm. of iron dissolved in 2·5 c.c. of nitric acid and 2·5 c.c. water—"the sulphur was found to be without any influence."

It is quite evident, therefore, that the above conclusion rests entirely upon the assumption that the sulphur, which of course is present in the steel as a sulphide of iron, is oxidised to SO_3 , and will be present in the solution as a sulphate.

From the fact that the quantity of sulphur usually present in steel is very small, and that it is exposed for a considerable time to the action of hot nitric acid, it may be very reasonable to make such an assumption, but that it is not quite the case anyone can soon satisfy himself by experimenting upon any special steel containing a considerable quantity of this element. The sulphur is really liberated as such, and remains suspended in the fluid, thereby communicating to it a certain turbidity or milkiness, particularly striking in the case of low carbon or "mild" steels. This peculiarity enables one to select from a miscellaneous lot of samples all that are likely to be abnormal in the proportion of sulphur.

Pure Swedish steels which contain mere traces of sulphur dissolve in nitric acid of 1·2 sp. gr., and after the usual twenty minutes heating in boiling water are always found to be perfectly clear and brilliant; common steels, in which the sulphur may reach, say, 0·05 per cent, give a solution so decidedly different in clearness that they can be readily distinguished from each other. More noticeable still does the influence of the sulphur become when it is present to the extent of 0·1 to 0·2 per cent, and in a "steel" with 0·50 per cent it is quite impossible to make any satisfactory adjustment of the tints.

In the experiment tried by Prof. Eggertz, and referred to above, the sulphur added as magnesium sulphate is equal to one per cent; if a "steel" actually containing this quantity had been used, instead of finding it to be without any influence, it would have been found quite impossible to compare it with any ordinary standard.

A very simple experiment showing how the colour estimation is influenced by the presence of suspended matter

in the liquid, may be tried by taking a highly diluted solution of ammonium sulphide to which an excess of nitric acid has been added; this solution will be quite milky, owing to separated sulphur. If now a sample of pure Swedish steel be dissolved in the usual way and divided into two equal portions, and to one of them a drop of the above solution is added, an immediate increase in the colour intensity will be observed when the tubes are examined from above as they are held over a mirror.

Not only is the colour intensity altered, but the brilliant amber-coloured solution will be found to have acquired a distinctly browner hue, and this suggests that, apart from the difference of colour quality, due to slight variations in the condition of the carbon, sulphur also possesses an important influence in this respect.

Another interesting experiment is to take the solution of a common steel containing 0·05 to 0·1 per cent of sulphur and divide it into two equal portions and filter one of them; if they are now carefully compared with each other the result of the observation will be somewhat astonishing to those who may be under the impression that their estimations are reliable to within one or two hundredths per cent; the two solutions will be different both in quality and intensity. I would here point out that when an attempt is made to adjust the tints of two coloured solutions differing slightly in clearness or quality, if only a small portion of the liquid be looked through, as is done when looking across the tubes, the observer is often easily satisfied with his comparison; but if after having apparently adjusted the tints of the liquids in this manner he will look through a much greater depth of the fluid, his self-satisfaction will often disappear; the fact is that two coloured solutions, differing even slightly in quality, can never be exactly equalised.

This subject is one of great importance on account of its bearing upon the question of the proper selection of standards, and in conclusion it may be of interest to note that if a common steel is compared with a standard of pure Swedish, the colour intensity is sure to be over-estimated, and if the standard is of a common or impure steel the estimations in the purer samples will be too low.

The Laboratory,
John Spencer and Sons, Lim.,
Newburn Steel Works,
near Newcastle-on-Tyne.

VOLUMETRIC ESTIMATION OF BORACIC ACID, AND OF AMMONIA IN AMMONIA SALTS.

By J. McGLASHAN.

THE following is an account of some results obtained, using Poirrier's orange II. and orange III. as indicators, for the determination of boracic acid and ammonia in ammonia salts volumetrically.

In the first experiment with boracic acid four quantities of 2 grms. each were taken, dissolved in water, a few drops of the orange II. or orange III. solution added, and titrated with normal soda gave:—

With orange II. 99·6 and 99·8 per cent H_3BO_3

" " III. 99·8 " 99·8 " "

NaBO_2 being the salt neutral to both indicators.

In the next experiment 2 grms. of borax were taken for each determination, dissolved in water, and the boracic acid liberated by adding dilute sulphuric acid until neutral to methyl orange. A few drops of the orange II. or III. were then added, and standard soda run in until the yellow colour of the solution was changed to red.

Orange II. gave 38·3 and 38·4 per cent B_2O_3

" III. " 38·3 " 38·4 " "

estimating the Na_2O present in the borax, and calculating to B_2O_3 , gave 38·38 per cent B_2O_3 .

In estimating boracic acid in boracite or borate of lime, a weighed quantity of the mineral was heated in a flask with dilute sulphuric acid; when the decomposition was complete, caustic soda solution was added to the contents of the flask until neutral to methyl orange, and the insoluble calcium sulphate filtered off and washed. A few drops of orange II. or III. were then added to the filtrate, and the boracic acid titrated with normal soda.

Orange II. gave 45.6 and 45.5 per cent B_2O_3

" III. " 45.6 " 45.7 " "

This sample by analysis in the usual way gave 45.59 per cent B_2O_3 .

In this experiment, if the caustic soda used in neutralising is not free from carbonate, the contents of the flask must be boiled either before or after filtering to get rid of any carbonic acid that may be in solution; otherwise it will be estimated as boracic acid.

The presence of ammonia in any form other than the hydrate or borate is to be avoided. If ammonium borate is the salt in which the boracic acid is to be estimated, it may be done by adding standard soda to the solution right away. Free ammonia in a dilute solution acting as if neutral to the oranges II. and III., the change in colour taking place when the soda is in excess, so, by adding a standard solution of soda to an ammonia salt, it is possible to estimate the ammonia without distillation; of course this is not applicable to a mixture of ammonia salts. In the case of commercial ammonia salts, any free acid they contain must be neutralised before proceeding to estimate the ammonia. Two grms. of pure ammonium chloride were taken in each of the following experiments:—

Orange II. gave 31.5, 31.4, and 31.5 per cent NH_3

" III. " 31.5, 31.5, " 31.5 " "

With ammonium carbonate the end reaction was indistinct, the sodium carbonate formed being slightly alkaline to both oranges. Titrating sulphuretted hydrogen with caustic soda, using oranges II. and III. as indicators, the end reaction was sharp; NaHS being the neutral salt. With arseniates, oranges II. and III. gave an indistinct end reaction. For the purpose of comparison it will be found convenient to keep a beaker alongside containing water with a few drops of the indicator or indicators added, and made alkaline with a drop or two of normal soda.

City Analyst's Laboratory,
156, Bath Street, Glasgow.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING AUGUST 31ST, 1888.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, *Metropolis Water Act*, 1871.

London, September 4th, 1888.

SIR,—We submit herewith the results of our analyses of the 182 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from August 1st to August 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

As might have been expected, the unusual and irregular meteorological conditions of the past few months have had a certain influence on the waters of the Thames and Lea. We shall have to comment on this circumstance hereafter. We content ourselves now with remarking that the water supplied to London during a very exceptional summer, has been uniformly good and wholesome. Of the 182 samples examined by us during the month of August (excepting three samples of the East London Company's supply, which were recorded as "very slightly turbid"), the whole were found to be perfectly bright and free from any trace of suspended matter.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

RESORCINOL AS A TEST FOR NITRATES.*

By DAVID LINDO.

Reagents.

AN aqueous solution of resorcinol, 100 c.c. contained 10 grms. of the phenol.

Solution of HCl about 15 per cent.

Pure concentrated sulphuric acid.

0.5 c.c. of nitrate solution taken for each test. 1 drop HCl, 1 drop resorcinol solution, and 2 c.c. sulphuric acid. Test-tubes $\frac{3}{8}$ inch employed. White background. Three or four tests made together at each dilution of N_2O_5 .

N_2O_5 dilution.	Reaction.
1,000,000	Faint purple, not sufficiently definite to be reliable even after long standing.
500,000	After some time a definite purple. Colour permanent.
100,000	At first purple-red; after an hour pronounced purple. Takes several hours to develop fully. A beautiful colour and very permanent.
50,000	After some time purple colour very intense. Lower portion of band fine purple-red.
20,000	After some time colour so intense can only be distinctly seen in the upper portion of band by transmitted light.
10,000	Colour so intense can only be seen distinctly in the lower portion of band. Vivid purple-red.

Remarks.—Without HCl resorcinol is not of the least value as a test for nitrates; with the addition of HCl it is perhaps one of the best reagents we possess for the purpose. It is fully five times more delicate than carbolic acid, and the final purple colour which the bands acquire is very permanent. The blanks with distilled water, HCl, &c., show a faint compound band, pink above, yellow below; this cannot possibly be mistaken for the definite purple band which the test gives with N_2O_5 , even at a dilution of 500,000. One drop copper solution (2 per cent sulphate) added to the test was found to increase the intensity of the band, but not to a very remarkable extent; the metal may therefore be dispensed with when this phenol is employed.

* For further details as to the method, which is the same as the author employed with other phenols in testing for nitrates, see CHEMICAL NEWS, vol. lvi., p. 1.

It would be premature to say that resorcinol is equal to the copper orcinol reagent as a test for nitrates, since the influence of other bodies on the reaction has not yet been studied. It appears to be a little more delicate for nitrous than for nitric acid; as a test for chlorates it is of little or no value.

Colour Reactions with Resorcinol and Oxidising Agents free from Nitrogen.

0.5 c.c. solution of the oxidising agent for each test, 1 drop resorcinol solution, 2 c.c. sulphuric acid. Tests made with and without addition of 1 drop HCl.

Potassic Chlorate.

1000 Cl_2O_5 Compound band orange top, intense blue soon changing to green below.
10,000 Cl_2O_5 The same, but much weaker.
With HCl As above, but weaker.

Potassic Dichromate.

Half grm. to 1 litre of water.
Red to buff-coloured top band, purplish lower band. On standing purple changes to pink or ruddy brown with HCl. If the sulphuric is run in at once, buff top band, lower narrow brown band. If the test is left to stand until it turns green before adding sulphuric, then red top and green lower band, red soon fades.

These double bands cannot be mistaken for the permanent purple band which N_2O_5 gives with the test.

Permanganate.

$\text{N}/_{10}$ with four volumes of water.
Dark orange top band, yellowish below.
With HCl, fine shaded compound band, orange-red top, greenish shade below.

Hydroxyl.

Solution sufficiently diluted gives green and brownish compound band.

Falmouth, Jamaica, B.W.I.,
September 10, 1888.

THE DISSEMINATION OF SULPHUR
AND PHOSPHORUS AS OBSERVED BY
ELECTRO-DISSOLUTION,
AND COMBINED WITH THE SECONDARY
EFFECTS OF ELECTROLYSIS.

H. N. WARREN, Research Analyst.

WHENEVER sulphur is caused to act upon metallic iron, under all ordinary circumstances there is produced the ordinary protosulphide of iron, of the formula FeS . Take, for instance, a pound of iron, in a liquid or molten form, into which a few grms. of sulphur have been introduced. Ordinary combination at once takes place. The product, after thorough incorporation has been attained, by either rotation or stirring, is for convenience sake obtained in the form of a rod by casting while still liquid, and afterwards attached to the positive pole of a compound battery, a platinum or thin copper plate being also attached to the negative, the whole being immersed in a dilute solution of FeCl_2 . On the circuit being completed the casting becomes gradually dissolved, the metal depositing upon the negative plate, thus giving rise to free acid, which again reacts on a fresh quantity of iron, the action proceeding as before. On withdrawing the stick of iron from the solution after the lapse of a few hours a quantity of black granular precipitate may be readily detached, which, after drying, has the ordinary composition of ferrous sulphide, FeS , since no sulphuretted hydrogen has been evolved.

The theory of such a reaction would thus tend to show

that the compound expressed by the formula FeS is the only combination obtainable by the simple action of sulphur on metallic iron, aided by heat, and that the sulphur does not disseminate itself throughout the whole mass of metal to form a compound possessing a formula where iron predominates largely, such as would be inferred from the formula expressed by Fe_3S , and which could be arrived at by calculating from analytical data; but exists rather in the form of sulphide of iron, disseminated, so to speak, through a mass of pure iron, the sulphide present forming a simple network allowing the current free passage; the iron being a much superior conductor of electricity than the sulphide, becomes more rapidly dissolved, leaving the residual sulphide.

The dissemination of sulphide of iron may be also readily observed by projecting sulphur on to the surface of molten iron, allowing the contents to solidify, and after cooling the same, dislodging the crust of sulphide of iron thus produced, leaving the iron below unaffected. But on repeating the experiment and thoroughly incorporating the same the sulphide formed in the first instance completely disseminates itself throughout the whole mass, leaving a more or less brittle regulus. Phosphorus may be entirely substituted for the sulphur in every instance, affording similar results, iron, nickel, cobalt, and all metals of the third group behaving more or less similar; the highest and most important phosphide of iron yet produced being apparently that represented by the formula Fe_4P , produced by the reduction of the phosphate at a high temperature in the presence of carbon. I have dissolved by the aid of electrolysis numerous prepared specimens of iron containing various percentages of phosphorus, the residues of which closely approach a formula of Fe_4P .

Percy, in his metallurgical treatise, describes several compounds of phosphorus with iron, to the lowest of which he attaches the formula Fe_{12}P . Considering then that Fe_4P is the highest obtainable phosphide, that expressed by Fe_{12}P is entirely composed of Fe_4P disseminated through a larger bulk of iron, and may be again separated by electro-dissolution.

With respect to silicon, the highest silicide of iron that I have succeeded in obtaining would assume a formula expressed by that of Fe_2Si while of carbon, according to Abel and Bloxam's treatise, the authors assert that iron never combines with more than six per cent of carbon, and they therefore represent the formula of carbide of iron by Fe_4C . Considering, then, that the above-mentioned elements exist when in combination with iron in the form of silicide, phosphide, sulphide, and carbide of iron, the following is a tabulated outline expressing the same result when calculated differently.

Result obtained by Ordinary Analysis of Sample Grey Cast-Iron of Excellent Quality.

Iron	94.946
Graphite	2.340
Manganese	2.370
Ni + Co	0.014
Li	0.230
Phosphorus	0.070
Sulphur	0.030
	100.000

Result as obtained in accordance with Various Electro-dissolutions.

Iron, Fe.	93.443
FeS.	0.083
Fe_4P	0.600
Fe_2Si	1.150
Mn.	2.370
Graphite	2.340
Nickel and Cobalt	0.014
	100.000

On making a like observation regarding the metals of the second group, exactly a reverse phenomenon presents itself, for on introducing sulphur into molten copper no dissemination of the sulphide of copper thus produced is manifested, but results in a nucleus of pure copper, imbedded or surrounded by a wall of cupric sulphide, the same result being also obtained by a similar treatment of most metals of the second group. On again returning to this particular form of electrolysis, the secondary results that may be afforded thereby are often of more interest than the so-called primary results, the particulars of which must, however, for the present, be deferred to a further article.

NOTE ON A NEW TEST FOR IRON.

By F. P. VENABLE.

A SOLUTION of cobalt nitrate to which strong hydrochloric acid has been added is blue. It was noticed that when some impure hydrochloric acid was used a green colour was gotten instead of the blue. This change was traced to the iron in the acid, and as I have seen no mention of it elsewhere, I venture to give the present notice of this test. It is very simple, rapid, and delicate for detecting traces of iron, and is especially useful in testing strong acids. The delicacy of the test is such that when even 3-100,000ths of a grm. of ferric salt are added to the blue strongly acid solution mentioned above, the green is clearly given. With a somewhat larger amount this green is quite vivid. If too much of the ferric solution is used the cobalt solution becomes pink from the addition of water. The test is not given by ferrous salts, nor does the presence of ferrous salts interfere with it. I have thought that the green was due to the addition of yellow ferric chloride to blue cobalt solution. Other yellow solutions which I have tested failed, however, to give the green.—*Journal of Analytical Chemistry*, Vol. i., Part 3, 1887.

THE USE OF COTTON AS A FILTER.

By A. B. CLEMENCE.

IN the estimation of silicon in pig-irons, a large portion of the time is taken in filtering off the silicon and graphite, especially in irons rich in silicon. If a filter-pump is not at hand, and a filter paper only is used, three hours are often taken for filtering and washing a solution that contains 3 or 3.5 per cent of silicon, and even when a pump is used, in which case a support must be used, the filtering is often tedious.

Having had occasion some time since to estimate the silicon in a large number of samples of iron rich in silicon, I looked for a quick filtering material, and in cotton I believe I have found all that could be desired.

The method of analysis is the "Sulphuric Acid Method," with, perhaps, some slight modifications.

One grm. of the borings are placed in a 6" evaporating dish, and 40 c.c. of a mixture of 1 part concentrated sulphuric acid and 5 parts nitric acid of 1.20 sp. gr. are added. A watch-glass is placed on the dish and set on an iron plate heated by a 6-inch multiple burner.

The dish may be left without care until the iron is dissolved and evaporated till the ferric sulphate has spattered on to the watch-glass. Water is now added and boiled for two or three minutes, when it is ready to filter.

The filter is made as follows:—A 3-inch filter-paper is folded as usual and the apex cut off, leaving a hole about $\frac{1}{2}$ -inch in diameter; a wad of cotton (the absorbent cotton of the druggists) is pressed into the apex, and, when wet,

may be, either with a pump or by the mouth, pressed tight enough to hold the residue. Even without a pump this filter will run so fast that close watching will be needed to keep the funnel full. Wash as usual with hot dilute hydrochloric acid and with hot water, when the residue, cotton and paper, is ready for the weighed crucible. Burning with a blast-lamp completes an estimation in forty minutes from the time of weighing the borings. The weight of the ash of the cotton will of course vary with the amount used, while that of the paper will be the same in each case, but it never need be more than 0.0005 grm., and this small amount may be disregarded when working on silicons for Bessemer charging.—*Journal of Analytical Chemistry*, Vol. i., Part 3, 1887.

THE STUDY OF MINERALOGY.*

By T. STERRY HUNT, LL.D., F.R.S.

1. OUR knowledge of the inorganic kingdom, as seen in this earth, may be comprehended under geography, geology, and mineralogy; the latter in its wider sense including all non-organised forms of matter, with their whole dynamical† (physical) and chemical history. In didactic language, however, mineralogy is limited to the study of native species, and includes a knowledge alike of their external characters and their chemical relations. The so-called natural-history method in mineralogy, disregarding these latter, is based exclusively on specific gravity, hardness, optical characters, texture, and structure, including crystallisation; while the chemical method regards the results of chemical analysis alone, and mixed methods consider these in connection with crystallisation, and even endeavour to take into account other physical characters. The defects of all the methods hitherto devised are obvious, and no system of classification can be complete which does not assign a value and a place to all characters whatsoever. There exists in the nature of things such an interdependence of these that a true natural system can exclude none. To the establishment of such a system, a clearer view of the nature and relations of physical and chemical phenomena than that generally received will materially aid us.

2. Matter is susceptible of changes of volume of two kinds. (1). Those produced from without, by variations of temperature and of pressure, which changes are constant and regular. Effecting no essential alteration in species, they may be called *extrinsic* or, as the result of external dynamic agencies, *mechanical* changes. (2). Those which have been described as due to "internal disturbances," which effect specific alterations in character. These constitute *chemical* or what may be called *intrinsic* changes, and differ from the last in that, instead of being constant and regular, they are periodic and subordinated to definite and unforeseen relations of volume. Intrinsic changes of volume in matter connote chemical as distinguished from dynamical processes. In chemical union we have intrinsic contraction or condensation (variously designated as interpenetration, compenetration, identification, integration, unification); and in chemical decomposition, intrinsic expansion or division. These changes may be either

* Read before the British Association, Bath Meeting, Section B.

† We use the words dynamics and dynamical in the sense in which they are employed by Thomson and Tait in their treatise on "Natural Philosophy," wherein all those manifestations of force which are neither chemical nor vital (biotic), including, besides ordinary motion, the phenomena of sound, temperature, radiant energy, electricity, and magnetism, are embraced under the general title of dynamics, corresponding to what in popular language is designated physics. Other eminent students of our time have sanctioned this use of the term dynamics, in which they were to a certain extent anticipated by Berzelius, who in 1842 included electricity, magnetism, light, and heat—all of which he regarded as affections of matter, and compared their phenomena with those of sound—under the common term of dynamides. (See Hunt, "Mineral Physiology and Physiography," p. 13).

homogeneous, involving one species of matter, or heterogeneous, involving two or more species. The first includes so-called polymerisation and depolymerisation, which may be described as homogeneous intrinsic union and homogeneous intrinsic division; constituting what we have called collectively *chemical metamorphosis*. Those intrinsic changes which involve two or more species we have included under the title of *chemical metagenesis*; the process being one of heterogeneous intrinsic union or of heterogeneous intrinsic division. In the former, intrinsic contraction involves volumes of unlike species, and in the latter, intrinsic expansion resolves a species into two or more unlike species. The relations to volume of all such changes are most simple and evident in the case of gases and vapours; but the same laws of intrinsic contraction and expansion by volumes apply alike to gases and to the liquid and solid species formed by their condensation. In all of these chemical changes temperature and pressure play an important part, and beyond certain limits the extrinsic or dynamic changes thereby produced themselves provoke chemical changes. These in their turn are accompanied by thermic changes, the study of which is the object of thermo-chemistry.

3. All chemically stable forms of matter may theoretically, by sufficient elevation of temperature, assume, even under the greatest pressure, a gaseous condition; the more or less polymeric vapours thus produced being subject to intrinsic expansion or depolymerisation on diminution of pressure. By reduction of temperature these pass, as may be seen under favourable conditions, through successive polymerisations, or processes of intrinsic contraction, into liquid (or solid) species; the passage from the vapour to the liquid being apparently continuous. The ideal gas is wholly obedient to the dynamic influence of pressure, according to Boyle's law, to which the ideal solid is wholly indifferent. These ideal forms are, however, constant only within certain limited ranges of temperature and pressure, beyond which even the so-called permanent gases become liquid or solid by intrinsic changes.

The regularity of the extrinsic variations in volume for gases and vapours, within certain known limits, enables us for such bodies to determine their specific gravity, for which purpose atmospheric air at 0° and 760 m.m. is taken as unity. If for this we substitute hydrogen gas (represented as $H_2 = 2.0$), the lightest body known, at the same temperature and pressure, the specific weight of an equal volume of any given vapour or gas, calculated for this standard temperature and pressure, is its equivalent weight, or in the language of the popular hypothesis, the molecular weight of the species. Extending the same method from normal gases and vapours to polymeric vapours, and thence to liquids and solids, and remembering that none of these forms are stable beyond certain ranges of temperature and pressure, we proceed to determine the specific gravity of all such bodies in terms of the same gaseous unit; the number thus obtained being for each body its equivalent weight. We thus find, as has long been suspected, that the equivalent (or so-called molecular) weights of liquid and solid species are exceedingly elevated. That of water, a litre of which at 100° (its temperature of formation under a pressure of 760 m.m.) weighs 958.78 grms., corresponds to 1192 volumes of water vapour at standard temperature and pressure ($H_2O = 17.96$) condensed into a single volume; or to $1192 \times 17.96 = 21,408$, approximately 21,400. Representing by $\bar{p}$ the empirical equivalent weight, which is really the specific gravity on the hydrogen basis ($H_2 = 2.0$), and by d the specific gravity taking water = 21,400 as unity, we obtain by the formula $\bar{p} \div d = v$, the reciprocal of the coefficient of the condensation which takes place in the passage of a normal gaseous species, by intrinsic contraction or polymerisation, into the liquid or solid species, the specific gravity of which we have determined by comparison with water.

4. The reciprocal number thus got is, as we shall show, one of great significance. In determining the specific

weight of any given liquid or solid species, the fact of prime importance is not simply its specific gravity as compared with water, but the relation of the value thus determined to the equivalent weight, or, in other words, to its specific gravity on the hydrogen basis. It is not d , nor yet $\bar{p}$, but the relation $\bar{p} : d$, as expressed by v . In the case of volatile species the true value of $\bar{p}$ may be known, but for the comparison of fixed solids, as oxides, carbonates, and silicates, we deduce from the received formulæ an arbitrary value for $\bar{p}$ by dividing the value calculated therefrom by twice the number of oxygen portions. Thus for MgO , $\bar{p} = 40 \div 2$; for SiO_2 , $\bar{p} = 60 \div 4$; for Al_2O_3 , $\bar{p} = 102 \div 6$; for $SiMg_2O_4$, $\bar{p} = 140 \div 8$; for $CCaO_3$, $\bar{p} = 100 \div 6$. For metalline minerals, including metals, and their compounds with S, Se, Te, As, Sb, Bi, the value assumed for $\bar{p}$ is that got by dividing the empirical equivalent weight by the sum of the valencies.

While the specific gravity of liquid and solid species is represented by d , the hardness, infusibility, and insolubility or resistance to chemical change are, for related species, directly as the condensation, or inversely as the value of v . This may be seen in comparing colourless ordinary phosphorus, $v = 17.2$, with the metalloidal form, $v = 13.2$; the isomeric silicates, meionite, $v = 6.5$, and zoisite, $v = 5.3$; or calcite, $v = 6.2$, with dolomite, chalybite, and diallogite, $v = 5.2$, and with magnesite and smithsonite, $v = 4.7$; for aragonite, $v = 5.55$. These examples will serve to show the relations between sensible characters and chemical constitution, the interdependence of which must be taken into account in a natural system of mineralogical classification. The differences in hardness and in solubility of the different species just named are familiar to chemists. The behaviour of native silicates with fluorhydric acid, lately studied by J. B. Mackintosh, illustrates in a striking manner the relations between condensation and solubility.

5. The successive forms imposed upon matter give us the order in which such a system of mineralogy should be built up. First, the form which we may call the *chemical form* of the species, either elemental or compound, due to the unknown stoichiogenic process, or to subsequent chemical metagenesis. Second, what may be called the *mineralogical form*, which involves the greater or less intrinsic contraction (polymeric condensation) of the normal chemical species—often gaseous or volatile, but frequently unknown to us—and the assumption by it of a liquid or solid state, having greater or less specific gravity, hardness, fixity, and insolubility, and being metallic or non-metallic, colloidal or crystalline. Third, the *crystalline form*, being the geometric shape assumed by the crystalline individual, which connotes a certain structure, apparent in the cleavage, the varying hardness, and the thermic, optical, and electrical relations of the crystal, but is, notwithstanding its value in determinative mineralogy, the least essential or most accidental form of the mineral species. The significance involved in the note of metallicity is very apparent when we consider the metallic and non-metallic conditions of selenium and of phosphorus, the similar dual conditions of the sulphides of mercury and antimony, the non-metallic and sparry characters of the native sulphides of zinc, cadmium, and arsenic, and the singular metallic character assumed by the complex tungstates or Tungstometalloids, known as tungsten bronzes. These, with the not less remarkably complex soluble tungstates or Tungstosanoloids, and the native tungstic species, make the Tungstates one of the most instructive orders known.

6. The author has elsewhere proposed to divide the mineral kingdom into four classes, including (1) Metalline, (2) Oxidised, (3) Haloid, (4) Pyricastate (combustible or fire-making) species. Each of these classes is again divided into orders, tribes, genera, and species. In the first class a single order includes two sub-orders and nine tribes, named (1) Metalloideæ; (2) Galenoideæ, including three sub-tribes, corresponding to sulphur, selenium, and tellurium compounds; (3) Bournonoideæ;

(4) Pyritoideæ; (5) Smaltoideæ; (6) Arsenopyritoideæ; (7) Spatometalloideæ; (8) Sphaleroideæ; (9) Proustideæ; each tribe including one or more genera. Again, in the second class are grouped, under different orders, Oxides, Silicates, Carbonates, Borates, Sulphates, Phosphates, Tungstates, &c. Three sub-orders of silicates include protoxide, protoperoxide, and peroxide silicates; among peroxide bases being reckoned aluminic, ferric, manganic, chromic, bismuthic, and also, for special reasons, zirconic oxide. Recognising in each sub-order various types designated Hydrospathoid, Spathoid, Adamantoid or gem-like, Phylloid or micaceous, and Porodic or colloidal; the tribes may be named Pectolitoïd, Willemoid, Amphiboloid, Talcoid, Ophitoid, Zeolitoïd, Felspathoid, Granatoid (garnet-like), Micoid, Pinitoid, Perzeolitoïd, Eulytoïd, Topazoid, Pyrophylloid, and Argilloid. Soluble saline species in any order are referred to a salinoid type, as Borosalinoid, Tungstosalinoid. The extension of this system to the Haloid and Pyricaustate classes is easy, and has been elsewhere explained.

The work of arranging in genera and species, with a Latin binomial nomenclature, and the determination for each species of the value of v , is now nearly completed for the first two classes; and the whole will probably soon appear, with a proper introduction, as a Systematic Mineralogy, to be followed by a Descriptive Mineralogy. The general principles here set forth are discussed at length in the author's "Mineral Physiology and Physiography" (Boston, 1886), pp. 279 to 401, where, in a chapter entitled "A Natural System in Mineralogy," will be found an examination of the constitution and relations of the known natural silicates arranged in tribes, and tabulated, with the calculated values of v , and a new quantivalent chemical notation. See further, a paper on "The Classification and Nomenclature of Metalline Minerals,"* discussing Class I., in the *Proceedings of the American Philosophical Society* for May 4, 1888, reprinted in the *CHEMICAL NEWS* of August 10 and 17; also the author's "New Basis for Chemistry," 2nd edition (Boston, 1888), where, in Chapters VII. and XIV., many points in the proposed mineralogical classification are elucidated.

MINERALOGICAL EVOLUTION.†

By T. STERRY HUNT, LL.D., F.R.S.

IN a paper read by the author in 1887, before the Geological Section of the British Association for the Advancement of Science, on "The Elements of Primary Geology," it was said that "the transformation of the primitive igneous material of the earth's crust through the action of air and water, aided by internal heat, presents a mineralogical evolution not less regular, constant, and definite in its results than the evolution apparent in the organic kingdoms."‡ The details of this complex evolutionary process, as explained by what the writer has named the crinitic hypothesis, have been elsewhere set forth at length, on more than one occasion, and involve the whole chemical history of the various mineral species which enter into the constitution of rock-masses, but especially their relations to subterranean changes under the influence of heated water, and to atmospheric action. As we have pointed out, the transformation of basalt into the hydrous porodic body known as palagonite, and the subsequent partial conversion of this into a crystalline zeolite, as described by Bunsen, furnishes a significant illustration of the process under consideration.

The stability of silicated species under atmospheric

influences is very variable, some being readily decomposed, and others very permanent; the indifference or chemical resistance, moreover, increasing with the hardness or mechanical resistance. These two qualities vary for species of analogous constitution directly as their condensation; while for species of similar condensation and hardness the chemical indifference increases as alumina takes the place of the ordinary protoxide bases, lime, magnesia, ferrous oxide, and alkalis—a fact readily explained by the comparative insolubility of alumina and aluminous silicates in atmospheric waters. The less partial action of dilute fluorhydric acid on the various silicates shows more clearly than the atmospheric process the relation of condensation to chemical indifference. This relation may be made evident by a few examples. The condensation being inversely as the so-called atomic volume, we find that when calculated by a simple formula (elsewhere given by the author) for all silicates and oxides this value (represented by $v (=p \div d)$ for the various felspars and scapolites, for nephelite, iolite, and petalite, equals 6·8–6·2; for the muscovitic or non-magnesian micas, 5·9–5·6; for garnet, epidote, zoisite, and the various tourmalines, 5·4–5·3; for staurolite and spodumene, 4·9; and for andalusite, topaz, fibrolite, and cyanite, 5·0–4·5, approximately. Comparing with these the common protoxide silicates, we find for wollastonite and willemite, $v=6·6$; for amphibole, 5·9; for pyroxene and enstatite, 5·5; for chrysolite, 5·4–5·3; and for phenakite, 4·6. In the sub-aërial decay of crystalline rocks, while felspars and scapolites among aluminiferous silicates are kaolinised, the micas, notwithstanding their laminated structure, are much less readily changed; and garnet, epidote, tourmaline, andalusite, and topaz are found unaltered with the quartz, corundum, spinel, cassiterite, and magnetite left behind by the decay of the felspathic rocks,—a process in which even amphibole, pyroxene, and chrysolite share. "The greater stability of those [silicates] which belong to the more condensed types is shown in their superior resistance to decay, and is thus of geological significance.

While the above are examples of the varying resistance to the atmospheric influences of carbon dioxide and water combined, other changes less well known take place in silicates by the subterranean action of watery solutions, where a greater insolubility determines the formation of certain softer hydrated magnesian and aluminous species by epigenesis from harder and more condensed species. The production of these epigenetic products, as was said in 1885, is due to their "chemical stability under the circumstances," and it was added, "The constancy in composition and the wide distribution of pinites show that it is a compound readily formed and of great stability. Such being its character, it might be expected to occur as a frequent product of the aqueous changes of other and less stable silicates. It is met with in veinstones in the shape of crystals of nephelite, iolite, scapolite, felspars, and spodumene, from each of which it is supposed to have been formed by epigenesis. Its frequent occurrence as an epigenetic product is one of the many examples to be met with in the mineral kingdom of the law of "the survival of the fittest." It is, however, difficult to assign such an origin to beds of this [described as dysyntribite and parophite], which are probably the results of original deposition or of diagenesis."

Mr. E. A. Ridsdale, who during the present year (1888) has done good service by publishing a suggestive essay called "Notes on Inorganic Evolution," speaks of the production and conservation of more stable species, as above described, as a gradual "selection of inert forms," and further, as "a survival of the most inert." But as inertness consists in stability, and in fitness to resist alike the chemical and the mechanical agencies which destroy other species, it is evident that his phraseology is but another statement of the formula of "the survival of the fittest."

The great principle of the change of the mineral matter

* An abstract of this paper, printed in the programme of the Royal Society of Canada, without revision or correction by the author, will also be found in the *CHEMICAL NEWS* for June 29, 1888.

† Read before the British Association, Bath Meeting, Section C.

‡ *Trans. Brit. Assoc.*, 1887, p. 704; also *Geological Magazine*, November, 1887.

which existed in former conditions of our planet, into other forms more stable under the altered conditions of later ages, is but an extension to the mineral kingdom of the laws already recognised in astronomical and biological development. As was written in 1884, "That a great law presided over the development of the crystalline rocks was, from the first, my conviction, but until the confusion which a belief in the miracles of metamorphism, metasomatism, and vulcanism had introduced into geology had been dispelled, the discovery of such a law was impossible." To this we may add that "the great successive groups of stratiform crystalline rocks mark necessary stages in the mineralogical evolution of the planet"; and that the principles which we have elsewhere laid down will help us "to recognise the existence and the necessity of an ordinary lithological development in time." The reader who desires to follow the questions here raised will find them discussed in the author's "Mineral Physiology and Physiography" (Boston, 1886), at much length in Chapters V., VI., VII., and VIII., and further noticed in the Appendix, p. 688, where will be found references to previous pages here cited.

NOTICES OF BOOKS.

The Analyst's Laboratory Companion. By ALFRED E. JOHNSON, Assoc. R.C.Sc.I., F.I.C., F.C.S. London J. and A. Churchill.

IN taking up this book we feared it might prove to be one of the numerous abridged manuals of analysis, qualitative or quantitative. Such is not the case; the author, who evidently addresses himself chiefly to public analysts, takes a less over-crowded track. We find, first, a notice on the precipitating powers of ammonium oxalate, barium chloride, sodium phosphate, and magnesia mixture. Then follow notes and indicators, a table of symbols and atomic weights (where we still find platinum figuring higher than gold), a table of formulæ, molecular weights and percentage compositions of commonly occurring compounds, a table of the molecular weights and weight of one litre of various gases, and a list of multipliers and their logarithms required in gravimetric analysis. It may here be asked whether such tables as those appended to Rose's "Quantitative Analysis" are not much preferable to this method?

Then follow multipliers required in volumetric analysis, notes on logarithms, and a table of logarithms from 1 to 1000.

Next the author gives weights and measures both on the English and the metric systems, and tables for their mutual conversion. Here, however, as in most works, there is no mention of the mutual relation of the c.c. and the grain measure.

Next we find tables "required in water analysis," evidently on the Frankland and Armstrong principle; tables of hardness in water; Sprengel's method for determining nitrates in water; tables for gas analysis, for the examination of beer, for the determination of phosphates, and for the conversion of nitrogen into ammonia and albumenoids.

As a novelty we notice a method for the quantitative determination of chicory in "coffee as in France." Then follow tables for Baumé's hydrometer; an alcohol table; tables of the actual quantities of the ordinary acids and alkalies existing in solutions of different specific gravities, and comparative thermometric tables.

Report of the Commissioner of Agriculture, 1887. Washington: Government Printing Office.

THE report of the chemist to the department is an extensive document, in which there are complaints, apparently well-founded, that the laboratory accommodation is meagre and

the number of assistants insufficient. "In a dingy basement, poorly lighted, not ventilated at all, the chemists of this division are compelled to work, in the winter straining their eyes in an all-day twilight, and in summer sweltering in a tropical temperature." The chemist to the department very justly holds that the analysis of ores, mineral waters, and other substances foreign to agricultural research, should not be required.

The report treats upon American beers, wines, ciders, and their adulteration. Strictly speaking, it might be contended that if fermented liquors are to be regarded as agricultural produce, so likewise should paper, leather, woollen or cotton cloth, &c. The use of brass taps and lead pipes in drawing beer is condemned as introducing appreciable quantities of zinc, lead, and copper. It is remarked that in wine fermentation at 15°—20° gives a product richer in alcohol but poorer in bouquet than if the temperature had been kept at 5°—15°. Only one sample of American wine has been found fraudulently coloured, the dye used being magenta. One sample of cider was heavily adulterated with sodium hydrocarbonate and with a sulphite.

The development of the sorghum sugar-industry has for a time been checked by a patent obtained by a former employé of the department.

It is contended that as the process in question was developed by this person at public expense, and whilst he was a paid servant of the nation, the process must belong to the nation.

The prickly pear plant with its thorns scorched off has come into use as a food for cattle, and is found to be very nutritious.

Annual Report of the Board of Regents of the Smithsonian Institution: Showing the Operations, Expenditures, and Condition of the Institution to July, 1885. Part II. Washington: Government Printing Office.

THIS publication, which appears nearly three years after date, comprises the reports of the Assistant Director, and of the Curators and Acting Curator.

The largest portion of the volume is devoted to an account of the "Catlin" Indian Gallery, which is now deposited in the National Museum attached to the Smithsonian Institution.

The book gives evidence of intense and most honourable activity in various departments of science, though we find no matter which falls within the scope of the CHEMICAL NEWS.

The Chemical Analysis of Iron. A Complete Account of all the best known Methods for the Analysis of Iron, Steel, Pig-Iron, Iron Ore, Limestone, Slag, Clay, Sand, Coal, Coke, and Furnace and Producer Gases. By A. A. BLAIR, Chief Chemist United States Board Appointed to Test Iron, Steel, and other Metals; Chief Chemist United States Geological Survey and Tenth Census. Philadelphia: J. B. Lippincott and Co.

THE author of this work informs us that his object has been to present within the compass of a single volume all the methods of real value to the iron-analyst. His work pre-supposes "some knowledge of general and analytical chemistry, and some practical experience in laboratory work and manipulation." He hopes thus to "facilitate in some cases the work of iron-chemists, to whom often very little is given, and of whom very much is required," a position, we must add, by no means unique.

Under the head "Methods for the Analysis of Pig-iron, Bar-iron, and Steel" we find directions for the determination of sulphur (including a "rapid" method), of silicon (also with a "rapid" method), of slag and oxides, of phosphorus (with a "rapid" method), of manganese, carbon, graphitic carbon, combined carbon, titanium, copper, nickel and cobalt, chromium and aluminium, arsenic, antimony, tin, tungsten, and vanadium. The "rapid method for sulphur is a volumetric determination

by iodine; that for silicon has been specially elaborated by Mr. S. Ford for this work, and is said to effect the determination of silicon, with an accuracy sufficient for all practical purposes, "in twelve minutes from the time the ladle is put into the molten iron."

The iron is first granulated by pouring into cold water, when the very appearance of the globules gives a clue to the proportion of silicon. If this impurity is abundant the drops will be almost globular, concave on the upper surface, and from $\frac{1}{4}$ to $\frac{3}{8}$ inch in diameter. If little silicon is present, as in spiegel and ferro-manganese, the globules will be elongated with tails about $\frac{1}{4}$ inch in length. The globules are dried in the hot ladle, crushed in a steel mortar, sifted with a fine sieve, and 0.5 grm. of the fine siftings are put in a platinum capsule with 10 c.c. of hydrochloric acid at sp. gr. 1.2, covered with a watch-glass placed over a flame, and the iron dissolved. When this is effected the watch-glass is removed, and the solution evaporated to dryness as rapidly as possible over an open flame. When dry, dilute hydrochloric acid is poured upon the iron chloride, and, as soon as all is dissolved, water is added; the contents of the capsule are poured upon a filter to which is attached a pump, filtered and washed. The filter and contents are placed in a tared platinum crucible, placed over a blast-lamp. As soon as the paper is burnt the crucible is laid on one side, the lid removed, so a small jet of oxygen is driven very gently into the crucible. As soon as the carbon is burnt the crucible is let cool and weighed; so the silicon originally present is calculated from the silica remaining in the crucible.

The "rapid" method for phosphorus is indirect, turning on the estimation of molybdic acid in ammonium molybdophosphates.

The author next gives methods for the analysis of iron ores. Here, in his directions for sampling, he directs that 2 lbs. should be taken for every 10 tons of the lot.

In the determination of total iron we are reminded that the residue insoluble in hydrochloric acid may still contain iron. Methods are given for bringing such refractory portions into solution.

In gas-analysis, which is considered at some length, Hempel's apparatus is recommended as generally preferable.

This work may, in fine, be pronounced a useful summary of a special and important department of analytical chemistry by an author of prolonged and wide practical experience.

Twenty-fourth Annual Report of the Alumni Association, with the Exercises of the 67th Commencement of the Philadelphia College of Pharmacy. For the year 1887-8. Philadelphia.

WE cannot find in this Report any chemical matter save a Synopsis of a Lecture on "Milk, its Composition and Analysis," by Prof. H. Trimke. Here we find the very just remark "that the way *not* to judge of the quality of milk is by means of the lactometer." Valuable matter which does not come within our scope—pharmaceutical, dietetic, and physiological papers—is not wanting.

Guide-Book for Distillers and Manufacturers of Arrack, Cognac, Gin, Rum, Cordials, Liqueurs, &c., &c. By E. SACHSE and Co., Leipzig, Distillers of Warranted Pure Essential Oils and Essences.

THIS pamphlet, which is accompanied with a wholesale price-list, and has evidently been not merely printed but drawn up in Germany, reminds us occasionally of "English as she is spoke." Witness such expressions as "carmin-surrogate," saffran "surrogate," "esmerald green," "oil of roses virrigin," "estragon," &c., which are assuredly not idiomatic English.

A much more important matter is the cross light which is here thrown into the recesses of the wine and spirit

trade. We find receipts for manufacturing claret, Hungarian wines (dry or sweet), Madeira, Malaga, Muscat Lunel, port, hock, sherry, and Tokay!

As a specimen we quote the formula for sherry:—To make up 63 gallons the operator is to take 3 lbs. essence for sherry, 5 lbs. honey, 4 pints sugar, syrup 7 gallons, 5 pints plain white wine, and 7 pints of superior wine-spirit 56 over proof.

Let the spirit-drinker should rejoice he will find that in concocting spirits and liqueurs "the best quality only of rectified spirit of potatoes (!) is to be used." The sugar to be used, both in wines and spirits, must not be "blued." In other words, the compounder must reject all sugars to which ultramarine has been added,—a trick not uncommon among the manufacturers of beet-sugar. Possibly we must be thankful that saccharine is not prescribed.

CORRESPONDENCE.

IMPROVED WASH-BOTTLE.

To the Editor of the Chemical News.

SIR,—The aphorism of the wise man of old that "there is nothing new under the sun" seems to be remarkably true as applied to wash-bottles. In January, 1881, I devised a new form of wash-bottle for producing a continuous jet for some time after ceasing to blow, and as it was generally approved I wrote a short account of the method of making it, and published it in the *CHEMICAL NEWS* of October, 28, 1881. Messrs. Becker and Co., of Maiden Lane, London, then took it up, and have made and sold wash-bottles of my pattern ever since.

I was not destined, however, to have the credit all to myself of having devised a new form of wash-bottle, as Mr. M. H. Foye, in the *CHEMICAL NEWS* of December 23, 1881, mentioned that he had contrived, about three years previously, a form of wash-bottle very similar to mine, the difference being principally that in his form the valve was on the *top* of the cork, while in mine it was at the *side*.

I was much amused, therefore, on looking through the *CHEMICAL NEWS* of last Friday to see my own form of wash-bottle exactly figured and claimed as a new device by Mr. Slatter. My original description was unaccompanied by a wood-cut, but from it any one can easily make a bottle for himself, as Messrs. Becker did originally.

The Royal College of Science, Dublin, has been peculiarly fertile in inventors of new forms of wash-bottles, three of us to my knowledge having brought out, no doubt independently, more or less new forms. That field, I think, is now virtually exhausted, and we must determine henceforth to go further afield in order to exercise our inventive powers withal.—I am, &c.,

ALFRED E. JOHNSON,

10, Victoria St., Wolverhampton,
October 9, 1888.

ANALYSIS OF NATURAL SILICATES.

To the Editor of the Chemical News.

SIR,—I should be obliged if some one would kindly inform me where I can find a description of the method for the quantitative separation of the minerals composing natural silicates.

I presume that acids are used in the first instance, and that the insoluble matter is in some way separately treated.

How, for instance, should basalts or schists be analysed so as to gain the fullest information about them?—I am, &c.,

E. DICKSON.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 11, September 10, 1888.

In What Stage of Oxidation do Chrome and Manganese Exist in their Fluorescent Compounds?—Lecoq de Boisbaudran.—In this lengthy paper the author seeks to show that in the ruby chromium must exist in the state of sesquioxide.

On the Indium Chlorides.—L. F. Nilson and Otto Pettersson.—The authors have obtained three distinct chlorides stable in the gaseous state. These are a trichloride, InCl_3 , a dichloride, InCl_2 , and a monochloride, InCl . It thus appears that a metal of the third group of the natural system of the elements may act as mono-, di-, and tri-valent in well characterised compounds.

No. 12, September 17, 1888.

The Compressibility of Gaseous Oxygen, Hydrogen, Nitrogen, and Air, up to 3000 Atmospheres.—E. H. Amagat.—At very high pressures oxygen, nitrogen, and atmospheric air have almost the same compressibility, which is of the same order of magnitude as that of liquids. At 3000 atmospheres it is approximately equal to that of alcohol under the normal pressure. The compressibility of hydrogen is much greater, nearly double. At 3000 atmospheres it is about equal to that of ether at the normal pressure.

On the Gallium Chlorides, and on the Value of the Elements of the Aluminium Group.—MM. Nilson and Otto Pettersson.—The vapour density of gallium trichloride is 8.84 at 360° , 6.11 at 440° , 6.14 at 606° , 5.18 between 1000° and 1100° . The density calculated on the formula $\text{GaCl}_3 = 6.081$; hence gallium trichloride reaches its normal gaseous state below 440° and begins to dissociate above 606° . The gallium dichloride, GaCl_2 , has the vapour densities 4.82 between 1000° and 1100° , and 3.56 between 1300° and 1400° . Aluminium and gallium displace 3 atoms, indium 2 atoms, and thallium 1 atom of hydrogen in dry hydrochloric acid. With the increase of the atomic weight there is an evident tendency of the elements of this group to form several combinations with chlorine. Aluminium has a single chloride, gallium at least two, indium three, and thallium four.

On Ferrous Chloride and the Chromium Chlorides.—MM. Nilson and Otto Pettersson.—Ferrous chloride appears to have a more complicated constitution at lower temperatures, and is resolved at a white heat into molecules of the normal composition FeCl_2 . The vapour density is 4.34 between 1300° and 1400° , and 4.29 between 1400° and 1500° . The density calculated for the formula $\text{FeCl}_2 = 4.375$. Two chromium chlorides are known to which the formulæ Cr_2Cl_6 and CrCl_2 are generally ascribed. The former has the vapour density 6.13 at 1065° , 5.51 at 1191° , 5.42 at 1277° , 4.82 at 1347° , 5.67 between 1100° and 1200° , 5.17 between 1250° and 1350° , and 4.58 between 1350° and 1450° . For the formula CrCl_2 the calculated vapour density is 5.47; above 1300° the density decreases. The authors have prepared Cr_2Cl_4 or CrCl_2 by heating chromic chloride in a current of pure dry hydrogen at a heat below that at which the glass of the tube becomes incandescent. Its vapour density is 7.80 between 1300° and 1400° , 7.27 between 1400° and 1500° , and 6.22 between 1500° and 1600° . The calculated density according to the formula $\text{CrCl}_2 = 4.256$.

No. 13, September 24, 1888.

This issue contains no chemical matter.

Bulletin de la Société Chimique de Paris.
Vol. xlix., No. 11.

Determination of Total Nitrogen in Organic Substances.—MM. Cazeneuve and Hugounenq.—The authors place at the end of the combustion-tube for the length of 15 c.m. dry manganese carbonate. After having charged the rest of the tube as usual expel the air in the following manner:—Connect the combustion-tube with an air-pump by the intervention of an abductor tube 12 c.m. in length, suitably bent and connected with the combustion-tube by means of a caoutchouc stopper. An ordinary T manometer tube is introduced in the connection of the tube and the pump. Exhaust three times in succession, liberating each time carbonic acid from the manganese carbonate until the mercurial column has completely descended. Without ceasing to liberate carbonic acid connect the combustion-tube with the Dupré apparatus; collect pure carbonic acid, and then proceed with the combustion as usual.

Determination of Total Nitrogen in Urine.—MM. Cazeneuve and L. Hugounenq.—The authors recommend the method of Dumas with their modification, as above described, in preference to the Will-Varrentrapp and the Kjeldahl processes.

New Method of Determining Carbonic Acid in Solution.—Leo Vignon.—This paper will be inserted in full.

Thermo-chemistry of the Diazo-compounds.—Leo Vignon.

The Formation-heat of the Acetyl-acetonates and of Some Homologues.—Alphonse Combes.—These two papers do not admit of useful abstraction.

The Properties of Sodium Disulpho-persulphate.—A. Villiers.—This salt forms orthorhombic crystals soluble in 1.3 part of water at 15° . If re-dissolved in water they crystallise at ordinary temperatures in the anhydrous state, but take up two mols. of constitutional water if the liquid is refrigerated. The anhydrous salt is permanent in the air. It melts at 125° and at 140° it gives off sulphurous acid. The residue consists of sodium sulphate and sulphur, but no alkaline sulphide.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 3.

Collection of the Specific Gravities of Aqueous Solutions.—A very useful memoir, but not capable of abridgment.

The Chemical Character of the Peptones and their Separation from Normal Albumen.—R. Palm.—The term peptone must signify a solution of protein in acids, chiefly in sulphuric and acetic acids, and probably in other acids. Potassium xanthogenate may serve to distinguish peptones from normal albumen. With the former it gives a precipitate at once, but with the latter only on the addition of on acid.

Analysis of Pure Wines from Alsace-Lorraine, of the Vintage 1886.—Dr. C. Amthor.—Of no general interest.

Improvement in Washing-Bottles.—J. Sobiecky and V. Höbling.—This memoir cannot be reproduced without the accompanying cut.

Apparatus for and Methods of Gas-Analysis.—This paper cannot be usefully reproduced without a number of illustrations.

Distillation. Prevention of Bumping.—A. Reissmann.—The author recommends the use of spirals of thick platinum wire filled with pieces of pumice-stone.

Prevention of Frothing.—H. Künz.—The author adds a little solid paraffin.

Small Laboratory Apparatus.—Notice of improved filters, washing-bottles, &c.

New Reagent for Salts of Copper.—Aliamet.—A solution of neutral sodium sulphite in which a little pyrogalllic acid is dissolved, and which gives an intense blood-red solution in aqueous copper solutions of medium concentration.

Separation and Determination of Phosphoric Acid and Tungstic Acid.—Fr. Kehrmann.— $1\frac{1}{2}$ to 2 grms. of the compound (free acid or alkaline salts) are mixed with double the volume of the calculated quantity of caustic soda and a sufficiency of water, and boiled for half an hour in a covered porcelain or silver capsule. The clear solution, when cold, is mixed with twice the quantity of ammonium chloride which will furnish chlorine to combine with the alkali present, placed in a beaker, and, after adding one-fourth of the volume of ammonia, precipitated with magnesia-mixture. After standing for twelve hours it is filtered and washed with dilute ammonia to which a little ammonium nitrate has been added. To remove any traces of alumina and traces of ferric oxide the ammonium-magnesium phosphate is again converted into *Sonnenschein's* precipitate. The ammoniacal filtrate containing the tungstic acid is evaporated down upon the water-bath in order to expel free ammonia, and separated from the tungstic acid by desiccation with hydrochloric acid repeated at least four times. The tungstic acid is then perfectly washed by decantation with water acidified with a little nitric acid and mixed with a little ammonium nitrate, ignited at a dull red heat until the weight becomes constant, and weighed.

Detection of Sulphites in Presence of Hyposulphites and Sulphates.—A. Villiers.—From the *Bulletin de la Société Chimique*.

Detection of Nitrogen Compounds in Seleniferous Sulphuric Acid.—G. Lunge.—In case of a seleniferous sulphuric acid free from nitric acid the author observed the following reactions:—On adding a solution of diphenylamine in strong sulphuric acid there appeared at first no colouration. If a little water is stratified upon the acid mixture there appeared exactly the same "corn-flower blue" colour as in case of a sulphuric acid containing nitrogen acids. If seleniferous sulphuric acid is superstratified with solution of ferrous sulphate there appears firstly the same phenomenon as in presence of nitrogen acids, *i.e.*, a brownish yellow or yellowish red ring at the point of contact. This does not, however, disappear on warming, but becomes thereby, or on prolonged standing, darker, and the liquid is filled with red reduced selenium.

A General Reaction of the Polyatomic Alcohols.—D. Klein.—From the *Comptes Rendus*.

Detection of Saccharine.—Herzfeld and Reischauer.—The authors, after acidulation with phosphoric acid, extract the saccharine from sugar with ether and evaporate with ether.

Detection and Determination of Acetic Acid in Presence of Formic Acid.—D. S. Macnair.—From the *CHEMICAL NEWS*.

Determination of Nitrogen in Organic Matter.—B. B. Ross and L. W. Wilkinson.—From the *CHEMICAL NEWS*.

Determination of Oxalic Acid.—MM. Berthelot and André.—From the *Comptes Rendus*.

Behaviour of Toluidines with Phosphoric Acid.—L. Lewy.—For the quantitative determination of ortho- and paratoluidin in a mixture, they may be weighed as phosphates and the phosphoric acid determined.

Separation of Paratoluidin Ortho- and Metasulphuric Acid.—E. A. Schneider.—From the *American Chemical Journal* and the *CHEMICAL NEWS*.

Determination of Ammonia in Urine.—C. Wurster.—The author abbreviates the process of Schlösing by expelling the ammonia at 50° at a reduced pressure.

Determination of Mercury in Urine.—C. Brasse.—The author steeps a piece of fine brass wire gauze for

twenty-four hours at 80° in 100 c.c. of acidulated urine, expels the mercury, adhering to the brass by heating in a porcelain crucible, and lets the mercury deposit upon a refrigerated gold cover.

Detection of Alcohol, Acetone, and Aldehyd in Animal Liquids.—P. Albertoni.—The author uses the iodoform test, the reactions of Vitali and of Legal and the examination of the reductive power with solution of silver.

The Precipitation of Albumenoids by Salts.—S. Lewith.—Of the salts examined the most active are:—Potassium chloride and acetate, sodium chloride, sulphate, nitrate, chlorate, ordinary phosphate, and acetate, calcium chloride and nitrate, and magnesium sulphate. The author has not extended his enquiries to the salts of aluminium.

Detection of Egg-Albumen, Propeptone, and Peptone.—C. Possner.—The author uses a modification of the biuret test.

On Mucoid Substances.—O. Hammarsten.—An examination of the mucine of the salivary gland of the lower jaw.

Moniteur Scientifique, Quesneville.
Series 4, Vol. II., August, 1888.

On Saccharine.—Dujardin Beaumetz.—In these two memoirs the author, whilst admitting the medicinal value of saccharine in certain cases, protests against its use in articles of food. It retards the action of the gastric juice upon albumenoid substances, as well as the saccharification of starch by ptyaline. The experiments of Dr. Worms prove that in some persons the prolonged ingestion of saccharine in small doses is followed by pains in the stomach and disturbed digestion. These symptoms ceased when the saccharine was discontinued and reappeared on its resumption. Saccharine has already found its way into the hands of sophisticians. The Academy of Medicine has formally concluded that saccharine must not be regarded as a food, but merely as a medicine.

On the Greater or Less Facility with which Glass may be Worked with the Gas-blowpipe.—Dr. Otto Schott.—Certain kinds of glass, if worked before the lamp, become dull and wrinkled on the surface, and cannot be brought to the desired form. On the contrary, the glass made in the Forest of Thüringen can be softened and hardened again, can be blown and melted repeatedly without any alteration in its appearance and in its texture. The glass-manufacturers of the district maintain that this property is due to the use of a peculiar sand, found at Martinsroda, and that all other kinds of quartz sand, especially the pure sands of Brandenburg, are unfit for use. The Martinsroda sand is found to contain 3.66 per cent of alumina. The glass made with this sand contained 3 per cent of alumina. Synthetic experiments confirmed the conclusion that the especially workable quality of the Thüringen glass is due to alumina.

Indirect Determination of Alcohol in Beer.—D. Sidersky.—The author gives a method of determining the alcohol in beer, based upon the difference of density before and after the expulsion of the alcohol. On expelling the alcohol from beer by boiling until it is reduced to half its volume, and then making it up to its original volume with distilled water, we have a liquid of greater density than the sample of beer. If we call *d* the density of the beer not boiled and *D* that of the beer freed from alcohol, the difference, *D*—*d*, will express the increase of the specific gravity of the beer in consequence of the replacement of a certain volume of alcohol by distilled water. If we execute the same operation with a mixture of water and alcohol containing the same proportion of alcohol as the sample in question, we shall evidently have the same increase of density due to the replacement of the same quantity of alcohol by water. If we take distilled

water at 15° as the unit of density and calculate the proportion of alcohol per cent, we have the equation—

$$D - d = 1 - X,$$

in which X expresses the density of a mixture of water and alcohol of the same proportion as the beer in question. Hence we deduce $X = 1 + d - D$, and find in Gay-Lussac's alcoholometric tables the degrees corresponding to the density X, represented by the value $1 + d - D$, D and d having been determined by direct experiment.

Purification of Crude Alkali and Simultaneous Production of Ammonia.—T. T. Mathieson and Jos. Hawliczek.—The compounds of cyanogen formed in the fusion of soda or potassa on the Leblanc process are commonly eliminated either by heat or by oxidation with an alkaline nitrate. In either case the nitrogen is lost. The authors, instead, treat the product of the fusion with steam at 300° to 500° . The nitrogen is thus liberated as ammonia, and may be collected in the usual manner. The crude soda, as taken from the revolver, is rapidly broken up and placed in the apparatus where it is to be steamed. It is let cool down to 300° to 500° , as [at higher temperatures the ammonia is destroyed, and superheated steam is introduced. When the ammonia ceases to escape the temperature is raised to 550° to 650° , and steam is again introduced, when the sulphur compounds are introduced in turn and the sulphuretted hydrogen evolved is collected and utilised in the regeneration of sulphur, or for any other purpose.

Vermillionette.—This pigment, sometimes erroneously believed to be a red ultramarine, is merely a red lake of eosine, and of course very perishable on exposure to light.

Patents issued at Berlin.—A list of German patents, relating chiefly to colouring-matters.

Determination of Carbon in Steel.—B. Blount.—From the CHEMICAL NEWS.

MISCELLANEOUS.

Metallurgical Department, King's College, Strand, London.—We are asked to state that there are three or four free admissions to the Laboratory and to the Lectures, obtainable through the City and Guilds Institute for the promotion of Technical Education. Enquiries may be addressed direct to Prof. Huntington at King's College. Work commences this week. The course of Lectures is designed for all those who in any way have to do practically with the applications of metals. It treats of the principles of the methods by which metals are obtained from their ores, and the means by which they are rendered suitable for the various requirements of the Arts. Especial attention will be devoted to the Metallurgical requirements for the Technological Examinations of the City and Guilds of London Institute in Metal Plate Work, Plumbing, and Iron and Steel, and for Whitworth Scholarships and Science and Art Department Exhibitions. The instruction given to each student in the Laboratory is regulated by his special requirements.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Cleansing Stone.—Perhaps some of your scientific correspondents will kindly inform me through the CHEMICAL NEWS if there is any other method of cleansing stone which has been exposed to the smoky atmosphere of Manchester than the unscientific process of scouring with stone and grit, thereby damaging the sharp arises and finely carved portions? A weak solution of fluoric acid is found to be effectual in removing this grimy deposit from glass, through the action of the acid on the glass itself, but is entirely powerless in its action on stone. Painting is objectionable because of its stucco appearance when done.—J. R.

Now ready, Crown 8vo., cloth, 5s.

THE ANALYST'S LABORATORY COMPANION. By ALFRED E. JOHNSON, Assoc. R.C.Sc.I., F.I.C., F.C.S., First Prizeman in Chemistry, Physics, and Mathematics of the Royal College of Science for Ireland.
London: J. and A. CHURCHILL, 11, New Burlington Street.

This day, Crown 8vo., 7s. 6d. cloth (post free).

THE METALLURGY OF GOLD: A Practical Treatise on the Metallurgical Treatment of Gold-bearing Ores, including the Processes of Concentration and Chlorination, and the Assaying and Refining of Gold. By M. EISSLER, Mining Engineer, formerly Assistant Assayer of the U.S. Mint, San Francisco. With 90 Illustrations.

London: CROSBY LOCKWOOD and SON,
7, Stationers' Hall Court, E.C.

A Gentleman who has had Four Years' Experience in the Chemical and Physical Laboratories of the Yorkshire College desires suitable practical employment in connection either with Arts or Manufactures. Can furnish satisfactory testimony as to character and capacity.—Address, X. Z., 26, Ramsden Street, Huddersfield.

A German Dr., Analytical and Manufacturing Chemist, thoroughly acquainted with the manufacturing of all mineral colours, as Zinc and Lead Chromes, Chrome Greens, Prussian Blue, Vermillionettes, Wood and Ceraline Lakes, and some new fast Violet, Green, and Red Alizarine Lakes, is open for a situation. He is, as well, a perfect Analyst, and well up in all kinds of Industrial and Agricultural Analysis.—Write "Analyst," May's Advertising Offices, 162, Piccadilly.

Required, in a London Assay Office, a Pupil Assistant. Small Salary offered.—Address, "Litharge," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

WANTED.—An Analytical Chemist for a Soap Factory. Must have had practical experience, and be able to advise re Scenting and Finishing Household Soaps, and also be well up in Manufacturers' Soaps.—Apply, stating full particulars, to Box 444, CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Extractum Malti cum Diastasi, concentr. in vacuo parat., first class quality, supplied wholesale by the first Austrian Malt-extract Brewery, Bittmann Bros., in Raase, Austrian Silesia.

FOR SALE.—A PLANT for the Extraction of OIL and GREASE by Solvents. The premises can be let if desired.—Address, C., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

SALE of the SITE of the MARSH CHEMICAL WORKS, Liamsamlet, Swansea, near the Junction Station of the Great Western and Midland Railways, from which a siding runs to the Works. Stack 100 feet high. Area of land five acres. Rent £37 10s. Unexpired term 67 years. The Works were built at an elevation of 20 feet, thus giving ample space and depth for waste. For particulars and conditions of sale address Mr. J. E. Stevens, Solicitor, Swansea.

MANUFACTURING WATERSIDE PREMISES IN LONDON.—Wanted, Ground Floor, with Boiler and Engine and use of slip of land 120 yards long.—Address, M. W. 450, Messrs. Deacon's Leadenhall Street, E.C.

MINERALS.—On Sale, an Extensive Collection of Minerals, comprising over 900 Specimens, in splendid condition, classified in Cabinet; also a few good Freestone Fossils. For particulars, &c., apply to Robert Richardson, South-owram, near Halifax.

CROSSE HALL MILLS, CHORLEY.

JOSEPH SMITH has received instructions from the Trustees of the Estate of re Thomas Forrester, to **SELL BY AUCTION**, at the above Mills, on WEDNESDAY, 17th of October, 1888, and following day if required, the whole of the truly Valuable **MACHINERY, PLANT, STOCK-IN-TRADE, Farm Produce, Horses, Lurries, Carts, and other Effects**.

Sale to commence at 10.30 each day.

Catalogues and further particulars may be had from Messrs. Boote and Edgar, Solicitors, 18 and 20, Booth St., Manchester; Messrs. Barrow and Smith, Solicitors, Brazennose St., Manchester; Messrs. Handley and Wilde, 44, Booth St., Manchester; Messrs. Davies and Crane, 5, Winckley St., Preston; or from the Auctioneers, Town Hall Sale Rooms, Chorley.

WEGELIN AND HÜBNER, Halle-on-Saale, MACHINE WORKS AND IRON FOUNDRY.

Representatives: NICKELS & Co., 150, Holborn, London, E.C.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37746,
with increased effect through abolishing the noxious spaces; best
Air-Pump for Compression and Evacuation; useful effect up to 90
per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment,
with Attachment for Filtration with Exclusion of Air; in Wood,
Iron, or Bronze every desired size

Experimental Filter Presses

in Wood, Iron or Bronze.
Filtration Experiments, if desired, carefully conducted in
our Laboratory.

Steam Pumps & Transmission Pumps,
horizontal, vertical, mounted on column, Wall Pumps, Pumps for
Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids.
"Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or
Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids,
any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof,
i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c.
Also Small Ice Machines for Families, Laboratories,
Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure,
or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Com-
pound Steam Engines.
From 2—150 horse-power]

Steam Water Pumps,

newest, most approved Construction, taking up little room, and
especially suitable for placing in Wells, with great efficiency; up
to large sizes.

Compressors driven by Steam or Belt,
for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon,
Ether, Alcohol, Acetone, Water; in Iron or Copper. (Extraction
Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.
Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans,
and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin
Refineries, Resin Distilleries, Paraffin Works, Tar Dis-
tilleries, Extract Works.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1508.

ON THE ACTION OF INCANDESCENT PLATINUM WIRE ON GASES AND VAPOURS.

By Dr. W. R. HODGKINSON, F.R.S.E.,
and F. K. S. LOWNDES.

In a letter to *Nature* some weeks ago a short account of some experiments was given by one of us on the action of an incandescent platinum wire upon various gases and vapours. Since this publication we have considerably extended the experiments in several directions.

The apparatus used was in most cases extremely simple, consisting merely of a glass globe having two or three side openings. In the case of vapours, a vessel with two necks was used, through one of which a cork or glass tube conveying thick platinum wires was passed, the wires terminating inside the vessel in a coil of thinner material than the leads. The substance to be experimented upon was put at the bottom of the vessel and vaporised by a Bunsen burner. When a gas was under investigation three necks were required to the globe, one for the wires, as in the other case, the others as inlet and outlet respectively.

The globe having become filled with the gas or vapours, a powerful electric current was sent through the wire, sufficient to cause it to become white-hot, or just short of melting. It was maintained at this temperature for various lengths of time, and the effect on the gas and the platinum itself noted.

The first substance we experimented upon was chlorine. A stream of this was sent into the globe for some time in order to expel all the air. The wire was then rendered incandescent. Immediately, a white glow—not of very great magnitude—was seen to extend round the white-hot spiral of wire; that this was not due to irradiation or any optical effect was proved by its not retaining the same shape, and also by its extending more upwards than downwards, as a flame. The current was stopped after passing for about twenty to forty minutes in the various experiments.

The walls of the vessel were thus found thickly coated with a yellow deposit of platinous chloride, whilst on the platinum wire itself were formed very fine crystals of metallic platinum. Any substance, such as graphite, charcoal, or pieces of minerals, placed within the spiral during the experiments became coated with a brilliant deposit of the platinum crystals, which in these cases were very difficult to remove.

With vaporised bromine results differing considerably to the last were obtained. Platinous bromide was formed, but in much less quantity than platinous chloride in the case of chlorine, and no crystals whatever appeared. The flame, however, playing about the wire was much increased.

Iodine produced only a trace of platinous salt, no crystals, but a very large flame, which, indeed, upon making the flask very hot by external heat, filled the whole of the upper part of the vessel. In the spectroscopic no bright lines were visible, a continuous spectrum crossed by the absorption lines of iodine being produced. The production of the crystals of platinum in the experiments with chlorine point to the conclusion that the platinous chloride must have been in a state of vapour without decomposition, otherwise it could not have come into contact with the hot wire after being formed. It seems probable that it was formed on parts of the wire comparatively cool, and vaporised as soon as formed. On coming in contact with the hottest portions of the

spiral, which were probably far above its dissociation point, it is instantly decomposed, and the platinum deposited in the form of crystals. The formation of volatile chloride of platinum is quite unprecedented, and seems remarkable when we take into account both the instability of the platinum compounds under heat and the character of platinum itself.

To complete the series of halogens, we used for our next experiments fluoride of silicon, and in this series the greatest precautions were used to exclude moisture. The whole apparatus was allowed to stand for five hours over strong sulphuric acid. A stream of the gas was then caused to pass through for half an hour longer, having to flow, both on entering and leaving the globe, through strong sulphuric acid. There was not the slightest deposit of silica on either the globe or the tubes leading to it, proving that no moisture was present. After passing the current for some forty minutes, it was noticed that the top part of the globe was deeply corroded and the wire itself was covered with a mass of crystals of silicon, a large number of which had fallen and collected at the bottom of the globe. It seems quite certain that the corrosion of the vessel could only be due to liberated fluorine. If hydrofluoric acid had been present it would have indicated its presence by etching the glass before the wire was incandescent; and the formation of silicon crystals also points to the same conclusion.

(To be continued).

A NEW FORM OF SULPHUR DIOXIDE APPARATUS.

By the Rev. E. RATTENBURY HODGES.

I HAVE just devised a simple arrangement for the preparation of sulphur dioxide solution.

A Woulff's bottle, having two necks, is provided with two bent glass tubes, A and B, fitted in with corks in the usual manner. The tube A reaches nearly to the bottom of the bottle, the other end being attached by a short piece of indiarubber tubing to an inverted glass funnel, C. Beneath this latter, and resting on a wood block or ring of a retort stand is a small iron dish, D, whose diameter allows about the eighth of an inch of air space.

To set the apparatus in action, the bottle is two-thirds filled with water and the tubes are replaced. Fragments of sulphur are now put in the dish, lighted, and placed under the funnel, and the tube, B, connected with a Geissler filter-pump, which is put in action. By this means the SO_2 evolved is readily drawn into the water and dissolved. This method takes less time, and there is also less risk of breakage of apparatus than by that usually followed, *i.e.*, by the decomposition of sulphuric acid, a process not altogether free from danger to the operator.

Nottingham, October 10, 1888.

ANALYSIS OF THE ANCIENT MORTAR FROM THE ROMAN WALL OF LONDON.*

By JOHN SPILLER, F.C.S.

EARLY in June last I was permitted to inspect and take samples of the fine piece of old London wall recently discovered when digging the foundations of the new Post Office buildings in St. Martin's-le-Grand. It is in every way a splendid relic of Roman work, measuring roughly, so far as the excavations have extended, nearly 120 feet long by about 13 feet in total height, the thickness not having yet been ascertained. Built of squared blocks of Kentish Rag, interstratified pretty regularly at every fifth course by a double or, near the bottom, triple layer of red tiles, and bound together by a white mortar, which for strength and endurance far surpasses that commonly used in the present day.† The scientific interest attaching to its composition induced me to undertake its chemical analysis, whereby I might compare it with other ancient Roman mortars, particularly with that from the castrum of Burgh, which was reported to the Norwich Meeting of the British Association, 1868, as well as with other mortars of more recent date.

The plan of examination was to crush the mortar, pick out any large stones weighing more than a grm. (these being constituents of "concrete" rather than of mortar), and to act upon 50 grms. at least of the fair average sample with a good excess of very dilute hydrochloric acid (1 part concentrated acid to ten parts of water), giving sufficient time for all the lime to be dissolved in the cold, washing the sandy residue once more with diluted hydrochloric acid, and finally with water.

It is customary to say that the hydrochloric solution will contain all the so-called "soluble silica," but I found in this particular mortar that nearly 11 per cent more could be readily dissolved by digesting the sandy residue in a cold weak solution of pure caustic soda. This was to me an unexpected result, may indicate the presence of a decomposable silicate, and which ought to be taken account of in future analyses. It will necessitate a re-examination by this plan of the Burgh mortar when I have found an opportunity to collect further samples.

I may here state that two samples of ordinary builders' sand were digested with acid, washed with water, and then tested with soda, but neither of them gave any appreciable amount of soluble silica; whereas a twenty-years old mortar contained 0.65 per cent, and another mortar taken from a brick wall at Canonbury, said to be 100 years old, gave 1.1 per cent of (alkali) soluble silica. The London wall, giving ten times this amount, raises a question of some importance: Was pozzuolana brought from Vesuvius to London by the Romans, and employed with ordinary sand and lime in the manufacture of this mortar; or is the large amount of soluble silica or silicate now found therein the direct result of long contact, through many centuries, of plain sand and lime? Which of these possible explanations is the true one I am unable to say at the present moment. It will require extended research to settle the point, and a whole series of analyses will have to be made, not only of ancient Roman mortars, but of Norman and mediæval products, besides others of later date. The subject is one of paramount interest to architects and builders, and as I cannot find any record of "soluble silica" having been sought for in this particular manner, I venture to press upon the attention of my fellow chemists the importance of looking at the matter from my point of view.

To return to the analytical results: Carbonic acid was accurately determined by dissolving 50 grms. of the Roman mortar in dilute hydrochloric acid, and passing all the evolved gas through a train of potash bulbs and dry

potash tube. The hydrochloric solution, made up to the bulk of one litre, was parcelled out for the estimation of the several constituents contained therein, 250 c.c. being in most cases employed. The insoluble residue (sand and brick particles) was treated in the manner already described, when, as I have said, nearly 11 per cent (or, more exactly, 10.44 per cent, calculated on the weight of the mortar originally taken) was readily dissolved in the caustic alkali, whilst 0.52 only of so-called soluble silica was found in the hydrochloric solution.

100 parts of the Roman mortar (air-dried) gave:—

Sand and brick	46.48
Acid-soluble silica	0.52
Alkali-soluble silica	10.44
Alumina	3.00
Iron peroxide	0.48
Lime	20.02
Magnesia	0.76
Carbon dioxide	13.03
Sulphuric anhydride	0.37
Sodium chloride	trace
Water and loss	4.90

100.00

Probable Arrangement of the Constituents.

Sand	45.95
Brick particles	0.53
Alumina	3.00
Peroxide of iron	0.48
Carbonate of lime	27.73
Silicate of lime	15.19
Sulphate of lime	0.63
Carbonate of magnesia	1.59
Water and loss	4.90

100.00

The mortar was originally made up of about 3 parts by weight of sand to one part of dry lime. In modern practice it is usual to employ more sand and less lime.

PS.—It having been suggested in the course of discussion, by Mr. Walter F. Reid, that an admixture of powdered flints might account for the high percentage of soluble silica found in the mortar, this ingredient being supposed to be soluble in cold caustic alkali, I have since put this to the test of experiment, using a perfectly fresh flint from the chalk near Caterham, reducing it to a fine powder, and digesting with a five per cent solution of pure caustic soda. No more than a mere trace of silica was dissolved by 24 hours' contact in the cold. Another sample of flint behaved in exactly the same way, so that the suggested explanation does not hold good. On the other hand, a sample of mortar from the square Roman bath at Bath contained fully as much soluble silica as the London wall.

ARSENIC IN THE HOME.

By A. W. STOKES, F.C.S., F.I.C.

SOME few months ago I examined for a large firm of household furnishes, as well as for numerous private individuals, a number of samples of the then fashionable "Imitation Indian Muslins" and cretonnes. More than 100 samples were examined, and 23 per cent of these were found to contain arsenic in appreciable quantities. In all qualitative cases Marsh's test was used, and only such samples as gave within five minutes indications of arsenic were marked arsenical.

Several were quantitatively examined. The highest proportion of white arsenic found was 2½ grains per square yard.

The colours in which arsenic was principally present were the terra-cotta reds and the greenish browns.

* Read before the British Association, Bath Meeting, Section B.
† For further particulars of structure and measurement (with pictorial sketches) see the *Builder* of May 5 and the *Graphic* of May 19 last.

There being some doubt whether these materials would give off arsenical vapours, I made the following experiments:—

Some pieces of the arsenical muslins and cretonnes, measuring altogether 300 square inches, were placed in a glass tube $3\frac{1}{2}$ feet long and $\frac{3}{4}$ inch diameter, and air was forced through the tube for six hours. The air passed among the folds of the material, then through a smaller tube, kept red hot, and finally bubbled through some nitrate of silver solution. At the end of the six hours there was not the least indication of any arsenic having been evolved. The tube was then kept at a temperature of about 100° F. (blood-heat) for six hours longer while air was passing through the tube; again no arsenic was given off.

From this it would seem that under ordinary circumstances arsenic would not be evolved by such fabrics. Yet in two cases samples of these materials were brought to me by medical men, in which well-marked symptoms of arsenical poisoning were ascribed to their use. In one case some six or eight work-girls employed in making up some of this material were all taken ill with the same symptoms of arsenical poisoning. Of course, in such case the material, when pressed with hot irons, is heated far beyond blood-heat, and minute particles are detached and float in the air of the work-room. That the arsenic is held very loosely by the fabric was evidenced by dipping some of the fabric in water; plenty of the arsenic was at once taken up by the water. It would seem at first as if this might be due to arsenic having been used as a preservative for the size or starch present as "stiffening"; but then these muslins have no stiffening.

Wishing to see whether other materials were subject to arsenical colouring, I examined thirty other articles in use at home, including plushes, velvets, carpets, mats, linings, silks, druggets, and fringes.

In only one sample, a little flax mat of green colour, was there any arsenic to be found. This mat, which weighed 9 oz., contained 21 grains of white arsenic.

I found my infant playing, lately, with a small glazed cardboard box of a green colour that had once contained chocolate, and that had been obtained from one of the automatic supply boxes. After the manner of infants, he was occasionally sucking this. Out of curiosity I tested it, and found that the "surface-paper," measuring 5 inches by $1\frac{1}{4}$, contained $\frac{1}{16}$ of a grain of white arsenic.

In all these cases the quantity of arsenic found is small, and it may be, under ordinary circumstances, quite harmless; but in all cases its presence is quite unnecessary. Other colouring-materials could equally well be used in which there is no possibly noxious ingredient.

Of wall-papers submitted to me, 10 per cent are found to contain arsenic. This is a high proportion, but then only suspected samples are sent for analysis. One of my rooms I found thus papered.*

Omitting articles in which its occurrence has been purely accidental, arsenic has been found of late years to be present in some samples of muslins, cretonnes, wall-papers, playing-cards, the glaze of some enamelled stewpans, the paper of fancy boxes, and in some furs. These last are usually the furs prepared by amateurs.

So that we may picture an infant placed by an unfortunate concurrence of circumstances in a room covered with arsenical paper, having its cot draped with muslin or cretonne, fed on food prepared in a glazed saucepan, itself covered by a rug, and playing with some fancy box of sweets or toys, all of these containing a minute but unnecessary amount of arsenic.

One has no wish to be an alarmist, or in any way to harass trade, and it must freely be acknowledged that cases of any ill results whatever being traced to the use of

these articles are very rare. None the less, seeing how unnecessary they are, and how each year arsenic seems to be finding its way into new quarters, it seems advisable to stop its further progress. This can only be done by prohibiting by law, as in some other countries, the use of arsenic for producing colours. Neither the ultimate seller nor the purchaser can really protect himself, the trouble and the expense would be too great; but by making the manufacturer answerable the evil might easily be remedied.

DETERMINATION OF BROMINE IN SEA-WATER BY FRACTIONAL TITRATION.

By F. GUTZKOW.

THIS method of quantitative determination of bromine consists of three operations—

1. Separation of the bromine as cuprous bromide.
2. Conversion of the cuprous bromide into zinc bromide.
3. Titration by hypochlorite of sodium.

1ST OPERATION.—*Separation of the Bromine as Cuprous Bromide.*—I mix 250 c.c. of filtered sea-water from the Pacific Ocean, to which a drop or two of sulphuric acid has been added, with 100 c.c. of a solution containing 25 grms., more or less, of crystallised cupric sulphate. To this clear solution, in which the copper may be assumed to exist as cupric chloride, I add from a graduated glass a solution of ordinary good sodium sulphite, the strength of which I need not know, until the brown flocculent precipitate which each addition produces will dissolve more and more slowly. It is easy to find a point when the brown precipitate has dissolved by digesting, but the solution remains slightly turbid from shining crystals of cuprous bromide. The separation of crystals increases rapidly, cuprous chloride being also separated. An excess of sulphite of soda does not matter much. By heating to about 40° C. the green liquid becomes blue again. Then, after cooling by water, another addition of sodium sulphite is made, say one-third of the volume previously used, again heated until the blue colour distinctly reappears (about 70° C.); the flask is once more cooled by water and allowed to settle, after removing any traces of sodium sulphite remaining in the neck by shaking with the liquid. It is advisable to loosely cork the flask. It will be found that the precipitate of mixed cuprous chloride and bromide is an unusually heavy one, settling rapidly from a perfectly clear liquid, from which any little particles floating on the surface can be made easily to sink (by a glass rod or judicious shaking), so that the liquid may be decanted to almost the last drop after short settling. The solution has become strongly acid by the sulphuric and sulphurous acid formed through the reaction between cupric chloride and sodium sulphite. For the 250 c.c. of sea-water employed about 3 grms. of copper have been separated, varying in amount somewhat according to the temperature after heating and after cooling. Heating to the boiling point only increases unnecessarily the copper separated. The second addition of sodium sulphite I found necessary for removing the last trace of bromine. Now, in order to test if all bromine has been separated, I add to the decanted liquid another portion of sodium sulphite, say as much as the second time, heat and cool as before, treat the precipitate by zinc and hydrochloric acid, as will be described hereafter, filter some of the solution of zinc chloride obtained into a test-tube and test by one drop of the standard chlorine solution and chloroform whether, after shaking, the chloroform turns yellow. If it does not it is certain there is no trace left in the decanted liquid.

By these operations bromine can be very conveniently and completely separated in about ten minutes. Enough cupric sulphate ought to be added to form cupric chloride also from the sodium sulphite, as this is partially converted

* Neither are those who avoid wall-paper altogether safe. A lady some two or three years ago had her rooms painted, and covenanted with a Sanitary Decorating Company that they should use on the walls paint containing neither lead nor arsenic. Pieces of the moulding she brought to me contained both lead and arsenic in the colour.

into sodium chloride by the formation of cuprous salts. In analysing saline solutions other than sea-water, I ascertain the specific gravity and the corresponding percentage in sodium chloride from the tables, and reckon three parts of crystallised cupric sulphate for one part of sodium chloride, assuming all dissolved salts to be sodium chloride, as an excess of copper does not matter.

2ND OPERATION.—Conversion of Cuprous Bromide into Zinc Bromide.—This is accomplished by zinc with the addition of a little hydrochloric acid. The operation is an easy one, and would seem to require no explanation. But for the 3rd operation, the titration, I require a small volume, say 25 c.c., in our case. A judicious economy of water and acid is, therefore, imperative. The precipitate in the flask is digested with about 100 c.c. of cold water, to which about 1 gm. of sulphuric acid has been added. The settled liquid is decanted as before, the last portion over a very small filter. Any iron which the cupric sulphate may have contained is now reduced to a no longer appreciable amount, and the sulphurous gas much reduced. But in order to destroy the last trace of the latter, I add a few drops of sodium carbonate and spread the crystalline powder around the flask. After one or two minutes enough oxychloride will be formed to answer the purpose afterwards. Now I rinse the contents of the flask into a porcelain dish, using only a few cubic centimetres at one time; heat in a test-tube about 5 c.c. water, with $\frac{1}{2}$ c.c. hydrochloric acid, and filter over the small filter I had been using into the flask. A little more water applied to both filter and flask will clean both sufficiently. The dish is heated on a water-bath, and when by smell I detect no sulphurous gas, I add one large amply sufficient piece of zinc.

The white crystals will soon be replaced by copper and a clear solution of cuprous chloride in hydrochloric acid. The finished reduction I recognise by touching with the point of a glass rod first the liquid and then a drop of sulphuretted hydrogen water spread on a porcelain plate. Enough acid must be present to prevent the formation of oxychloride of zinc. The contents of the dish, copper and all, are filtered over a small filter, directly into a small graduated cylinder, and ought not to give more than 10 or 15 c.c. filtrate. The copper is then fully sweetened into another porcelain dish with about 25 c.c. of hot acidulated water, and the filtrate evaporated to about 5 or 6 c.c. with the addition of one or two drops of sodium carbonate, then made acid again and added to the 10 or 15 in the graduated cylinder, and the water used for rinsing the dish utilised to fill up to 25 c.c.

3RD OPERATION.—Titration by Hypochlorite of Sodium.—I must suppose that the chemist who takes interest in the subject treated here is acquainted or makes himself acquainted with what Fresenius in the sixth edition of his celebrated book remarks on titration of bromine. He will find that all these titrations are based on liberating bromine by chlorine and on the colour imparted by free bromine to water, or chloroform or other absorbent. My method offers nothing new in that respect. Generally chlorine water is used as standard solution, which is the most changeable liquid employed in volumetric analysis. Figuier removes the bromine liberated by boiling; Reimann by chloroform. In the first case it requires better eyes than mine to recognise colouring when there are only one or two milligrams of bromine left, and in the second, frequent removal of the chloroform is necessary; for, while the decolouration of a small drop of chloroform slightly coloured is a sure and delicate test, the change of colour in a highly coloured drop of chloroform is a very coarse one.

As standard solution I use hypochlorite of sodium or potassium, that is ordinary "Eau de Javelle," as prepared by druggists (by treating "chloride of lime" with sodium or potassium carbonate), containing, generally, from one to two per cent of chlorine, which may be set free by an acid. The slight excess of the carbonate employed does not interfere. I dilute one part of the commercial liquid

with five parts of water, and test its strength by a normal solution of potassium bromide, acidulated by sulphuric acid. This normal solution I prepare by dissolving 1 gm. potassium bromide in water, add diluted sulphuric acid containing about 2 grms. SO_3 and fill up with water to say one-half litre. Then I ascertain the bromine in a given volume either by argentic nitrate and chlorine gas or by titration with the standard solution of hypochlorite of sodium, which has been previously assayed for chlorine by one of the usual methods. Deducting the volume used for assay I dilute until the normal solution contains one milligram per cubic centimetre.

Although the standard solution of hypochlorite of sodium is by no means unalterable, still it is much less changeable than chlorine water. For instance, a solution prepared three weeks ago and indicating 100 m.grms. of bromine by 18.8 c.c., requires to-day 19.6 c.c., weakening by 4 per cent. This weakening is, however, no matter, as it amounts to only 0.01 c.c. per day for 25 m.grms. of bromine, and I recommend, in all cases, to test its strength immediately previous to the assay on the unalterable normal solution of bromine. This is preferable to its test by an iodide of potassium, &c., solution, which Fresenius ("Quant. Anal.," § 143, β), recommends, deviating in this one little instance from the fundamental principle of volumetric analysis expressed by him elsewhere, that the test ought to be made, if possible, always in the same manner as the assay.

The novelty of my method is a kind of fractional titration which allows to foretell the final reaction on an aliquot portion of the liquid, and—in the case of bromine—to compare the colour before and after addition of the chlorinated standard solution. This kind of titration is advantageous also for other determinations, especially those which have a very sudden final reaction, as, for instance, the analysis of caustic soda. For the last named kind of analysis I proceed as follows:—The apparatus consists of a flask provided with a well-fitting cork with two holes. Through one of these holes passes a little bent glass tube, stopping short at the cork inside and connecting outside with a rubber tube and clamp or "clip." Through the other hole passes a long funnel to nearly the bottom of the flask. I prefer the kind of funnel called thistle-shape, or better, poppy-head shape. It must hold 30 to 40 c.c. A mark by file or paper glued on shows when the funnel is filled with 20 c.c. I measure the solution of caustic soda to be tested and dilute to a round figure, say 100 c.c., add litmus and fill into the flask, opening the clamp. By blowing through the tube I raise 20 c.c. into the funnel and close the clamp. I note the stand of the burette, say = 0.00 c.c., add one drop of standard acid; the solution remaining blue, I may add four more drops for the 80 c.c. in the flask, because $\frac{1}{2}$ = 20 c.c. were not changed. I do so; find that I have been using 0.25 c.c. in five drops, that the liquid remained blue, and that I may add safely 4×0.25 or 1.25 c.c., including the five drops already given. I bring the burette to 1 c.c. to get at round numbers; still blue colour. I may add four more c.c., and do so, $\frac{1}{2}$ c.c. at a time, stirring with a little glass rod which I leave always in the funnel, and observe that with 3 c.c. the contents remained blue, but become red with $3\frac{1}{2}$ c.c. Now I know that the final reaction will occur between $3 \times 5 = 15$, and $3\frac{1}{2} \times 5 = 17\frac{1}{2}$ c.c. I open the clamp and run standard acid to the 15 c.c. mark of the burette, shake and wash the funnel by raising and lowering repeatedly the mixed liquid. I raise again to 20 c.c. in the funnel, close the clamp and begin my second test, adding, as before, 1 drop; the liquid remaining blue, I add 4 more. Still blue. I may, consequently, give 5×0.25 c.c. = 1.25 c.c. I do so, but only 0.10 c.c. or two drops at a time, because I know that I am approaching the final reaction below 17.5 c.c. Having added 0.30 c.c., the liquid remains blue, but turns red at 0.40 c.c. I may add 5×0.30 but not 5×0.40 c.c. I open the clamp and proceed as before, bringing the burette to 16.50 c.c. I raise again 20 c.c.

The following table will show how the observations may be conveniently noted, + and - signifying respectively blue and red:—

To the Whole.

		To the Volume.				Stand of

No. 3.	1 drop +	0'25	—	0'25		16'75
	+	—	—	3 drops		16'90

Everything being prepared, I pour 25 c.c. of my normal solution of potassium bromide through one of the funnels into the flask, raise 5 c.c. or $\frac{1}{2}$ to the corresponding mark in the cup, close the clamp, and assay in similar manner as described above.

c.c., probably already $5 \times 0.90 = 4.5$ c.c. I lower the stand in the burette to 3.75 c.c., which makes the contents of the graduated cup nearly as light as those of the other cup, open the clamp, mix and wash the cups as described above. As I know that I am very near the finish, I raise only to the 1 c.c. mark.

The following table will record the results of this assay in a better shape, + expressing increase, - decrease of colour. ? doubtful.

It will be observed that the one dangerous calculation in this titration was the fourth of No. 1, which brought me on a not perfect observation too near to the result. I choose intentionally this example for pointing out the danger of adding too much from the burette on the observation of the first fractional titration, when the second cup contains still colourless liquid and offers no chance for comparison of colours. The increase of colour becomes easily fallacious after a certain intensity has been obtained, but not the decrease. The record of "addition

allowed to the whole" ought to be based on certainty, which may be won by another fractional titration. The following table will explain how the titration ought to have been made:—

have been made:—

		Addition.			Stand of Burette. 0.00 c.c.

					3.75

To sum up, this kind of titration is based at the beginning on colouration, and toward the finish on decolouration of the fraction in the cup. As long as three drops are required to produce a decolouration, another fractional titration may be safely undertaken; but when already two drops change the colour decidedly, it is better to stop and proceed to the final test with chloroform. These remarks refer, of course, only to a standard solution of about the strength indicated here.

The titration of the 25 c.c. obtained from the 250 c.c. of sea-water is done in exactly the same manner as that of the normal solution of potassium bromide, except that the observation of the first drop from the burette requires special attention. In the presence of iron (from the zinc) or copper, both being under the circumstances ferrous or cuprous salts, no bromine will be set free until they have been converted by the chlorine into ferric and cupric salts. Therefore, before commencing on the fractional titration, I empty the 25 c.c. into the flask, add 1 c.c. chloroform, also one drop from the burette, shake, and observe whether the chloroform shows colouring. If it does, I evaporate the drop of chloroform by boiling the contents of the flask while keeping them in agitation, cool, return the solution to the graduated cylinder, fill up to 25 c.c., and titrate in the manner described above, adding the one drop from the burette used for colouring the chloroform to the account.

The more experienced analyst will, however, be able to recognise the first colour without requiring chloroform, and thus avoid boiling the solution previous to titration, which may cause a slight loss by evaporating some hydrobromic acid, unless sodium carbonate is added. For the titration, the solution has then to be made acid again. Whilst by this preliminary test traces of iron, manganese, copper, and sulphurous gas can be detected and made harmless, the presence of hyposulphite of zinc (formed by the action of sulphurous gas on zinc) affects the assay more seriously, as it is less readily oxidised, completely only when the titrated solution is boiled to evaporate the free bromine. This causes formation of hydrobromic acid—hence the necessity of guarding against the presence of sulphurous gas before zinc is added. Every analyst will judge what other substances may be present in his solution which might interfere, and how to remove them.

It remains to state that the titration, as described, may also be applied to a solution of zinc bromide and chloride obtained by reducing a precipitate of argentic bromide and chloride by zinc. But more zinc will be required than for the reduction of cuprous bromide and chloride. Argentic nitrate will precipitate 5 grms. of chlorine from

250 c.c. of sea water, while in the precipitate obtained in the manner described there are only $1\frac{1}{2}$ grms. For this reason, and on account of the comparatively large volume of the argentic chloride, it is less easy to obtain a small volume of solution for titration.

Fehling's method of partial precipitation by argentic nitrate, with its difficult settling and sweetening of the precipitate, and absence of a ready test for ascertaining whether the bromine has been completely separated, I leave out of consideration here.

The amount of bromine in the sea-water near the entrance to the Bay of San Francisco, determined in the manner described, is 67.5 m. grms. in one litre.—*Proceedings of the California Academy of Sciences*, 1888.

THE FOUNDATIONS OF CHEMISTRY.*

By T. STERRY HUNT, LL.D., F.R.S.

1. IN an essay published forty years since, in September, 1848, the present writer advanced as the "basis of a true natural system of chemical classification" certain views as to elemental and polymeric types which have since played an important part in the science of chemistry. Assuming as the primal or fundamental type, hydrogen, H_2 (of which both water and ammonia were regarded as derivatives), and following the lead of Auguste Laurent, who had already, in 1846, represented alcohol and ether as derivatives of water, H_2O , in which one and two portions of hydrogen respectively are replaced by C_2H_5 ,† the hydrocarbons methane and ethane were considered as derivatives of H_2 , in which one portion of hydrogen is replaced by CH_3 and C_2H_5 . The relation between these hydrocarbons and hydrogen, and between the corresponding alcohols and water, was then declared to be one of homology, and these views were subsequently maintained and enforced on many occasions.‡

2. In the same essay the writer insisted on the existence of condensed or polymeric types, the pentachlorides being "referrible to a triple molecule, represented by H_6 , while the corresponding trichlorides form a double molecule." The triple molecule was further said to be represented by the vapour of sulphur, then known only in its hexad form, S_6 , the anomalous density of which, as compared with that of oxygen, was explained as the result of polymerism or condensation, while a similar condensation was suggested as probable in the case of ozone. The derivation of monobasic acids from the type of water, H_2O , and the possibility of anhydrides of these, and notably of the nitric anhydride (soon afterwards discovered by H. Deville), was also maintained in this essay; while bibasic and tribasic acids were regarded as derived from condensed types corresponding to two and three molecules of water. Hydrogen, H_2 , was then both the prototype and the logue of the hydrocarbons and the chlorides, and water, H_2O , of alcohols, ethers, oxacids, and anhydrides.

3. There were thus enunciated in this essay, in 1848, two distinct and important conceptions: (1) Hydrogen, H_2 , is the primal chemical type, of which water and ammonia are derivatives, and to which both mineral and so called organic or hydrocarbonaceous types may be referred. (2) Besides this dual or normal type, repre-

* Read before the National Academy of Sciences, April 17, 1888. Reprinted from the *American Chemical Journal*, vol. x., No. 5.

† Being H_2O_2 and C_4H_8 in the notation then in use, in which $H=1$, $C=6$, and $O=8$.

‡ On some Anomalies in the Atomic Volume of Sulphur, &c., with Remarks on Chemical Classification, *American Journal of Science* (Sept., 1848), vi., 170 to 178; also, "On some Principles to be Considered in Chemical Classification," read before the American Association for the Advancement of Science, Philadelphia (1848), *Ibid.*, 1849, vii., 399; viii., 89 (also, v., 265; ix., 65; xli., 206); and further, "The Theoretical Relations of Water and Hydrogen" (1854), *Ibid.*, xvii., 194, and *Chemical Gazette*, 1854, p. 181; also, "The Theory of Types in Chemistry" (1861); *American Journal of Science* xxxi., 256, and Hunt's "Chemical and Geological Essays" (pp. 464 to 469).

sented by H_2 , there are also condensed or polymeric types, represented respectively by H_4 and by H_6 , S_3 , &c., the condensation being made evident by the increased density of the polymeric vapours. How the first of these conceptions, that of the typical relations of water and hydrogen, after having been maintained for some years, was at length adopted by Gerhardt, Brodie, and Williamson, in 1851—1852, is to-day a matter of history, and is set forth in the two papers of 1854 and 1861, already cited, in the latter of which will be found quoted a full recognition by Wolcott Gibbs of the writer's claims to priority. The second and not less important conception—that of condensed or polymeric types, as represented by the higher metallic chlorides and the dense vapour of sulphur—remained, however, apparently unnoticed by chemists until after its re-statement in 1854, when it was adopted by Ad. Wurtz.

4. Meanwhile the writer, in the essay already noticed, "On some Principles to be Considered in Chemical Classification" (read in 1848 and published in 1849), had still further considered this conception of polymerism with increase of specific gravity, which was then extended from vapours to solid species, and was illustrated by the allotropic modifications of carbon and of phosphorus. In 1853, an attempt was, moreover, made to show that the change from a gaseous to a liquid or solid species is itself subjected to the same general law of polymerism; while in 1867 it was maintained that vapours, and the liquid and solid products of their condensation, as in the case of steam, water, and ice, are to be regarded as distinct species, the latter two being polymeric or allotropic forms of water vapour; in a word, that all changes of state or condition in bodies are essentially chemical in their nature.* Similar views as to the chemical relations of gaseous, liquid, and solid species were thirty years later, in 1883, set forth by Prof. W. Spring, of Liège,† to whom my earlier discussions of the subject were unknown.

Continuing the line of inquiry thus begun, and followed at intervals during forty years, it is now proposed to consider briefly the relations of gaseous, liquid, and solid species to temperature and pressure, together with the phenomena of allotropism, of specific gravity, of hardness, and of chemical indifference; all of which, as we have elsewhere maintained, are intimately related to and dependent upon the principle of condensation then enunciated.

5. All chemical change, of which this polymerism or condensation is but one manifestation, is subordinated to simple relations of weight and volume, which are most evident in the case of volatile and gaseous species. Well-defined gases, such as hydrogen, nitrogen, oxygen, carbon monoxide, and methane, undergo, through a wide range of temperature, a constant regular change of volume, amounting for each degree centigrade to $\frac{1}{273}$ of their volume at 0° . Their coefficient of expansion not being sensibly affected by considerable variations of pressure (which, according to Boyle's or Mariotte's law, the temperature being constant, causes the volume to vary inversely as the pressure), it follows that if we know the weight of a volume of such a gas at any given temperature and pressure, it is easy to calculate what its weight should be at any other temperature and any other pressure; as for example at 0° and 760 m.m., which are assumed as the standards in studying gases and vapours. These regular and constant variations in the weight and volume of a species under changes of temperature and pressure characterise the perfect or ideal gaseous state of matter. This is, however, known to us only within cer-

tain limits, since recent experiments have shown that the gases mentioned above are by the combined action of cold and pressure reduced to the state of liquids which, although still more or less compressible, are not subject to Boyle's law, and, moreover, often present great and rapidly increasing coefficients of expansion by heat,—a point especially noticeable in liquids as they approach the critical point beyond which they pass, under great pressure, into dense vapours.

6. The ideal liquid, like the ideal gas, has a regular rate of thermic expansion, the coefficient of which, however, varies for the different species, and is apparently (like its compressibility) closely connected with the degree of condensation; that is to say, with the interval by which it is removed from the normal gaseous species with which it is connected through dense vapours of higher integral weight. Water and mercury are, within considerable ranges of temperature, nearly ideal liquids. The ideal solid is, like the ideal liquid, permanent through considerable ranges of temperature, within which it has a regular coefficient of expansion of heat. It is sometimes more and sometimes less condensed than the corresponding liquid species; thus ice is considerably lighter than water, and solid bismuth is lighter than the fused metal, while in the greater number of cases the solid is heavier than the corresponding liquid species. For such liquids as become denser in solidification, it is well known that pressure augments their temperature of fusion. Amagat, in accordance with this principle, has reversed the well-known experiment of liquefying ice by pressure, and has effected the solidification of carbon dichloride (hitherto known only in a liquid form) by a pressure of 900 atmospheres at 10° ; while benzene, which under standard pressure crystallises only at 0° , is solidified at 22° under 700 atmospheres. There is probably, however, according to Amagat, "a temperature above which solidification cannot be effected by any pressure; that is to say, a critical point of solidification, as there is apparently a temperature below which the body remains solid under the feeblest pressure."*

On the other hand, it appears from many experiments that, in the language of W. Allen Miller, "there exists for every liquid a temperature at which no amount of pressure is sufficient to retain it in liquid form."† In other words, all such liquids and solid species, if stable,—that is, not thereby undergoing heterogeneous dissociation,—when heated under sufficient pressure to a temperature which for each is called its critical point, pass, with a comparatively small augmentation of volume, into the condition of very dense vapour or gas. The distinction between liquid and gas just above the critical point is, according to Andrews, impossible, and, in the language of Ramsay and Young, "would also disappear below the critical point, were it possible to follow the continuous change from liquid to gas."‡ In fact, the passage from the perfect or ideal gas proceeds through successively denser unstable polymeric gaseous or vaporous species, often more or less intermingled with one another, and perhaps also through unstable liquid species, into the ideal liquid or the ideal solid species.

7. We assume for the unit of volume in chemistry 1000 c.c., or 1 litre, and for the unit of weight that of this volume of hydrogen at 0° and 760 m.m., which equals very nearly 0.0896 gm., or, according to the determination of Regnault in the latitude of Paris, 0.089573 gm. In hydrogen, which through a wide range of temperature and pressure retains the properties of a perfect or ideal gas, we have a standard of weight upon which is built the stoichiometry of modern chemistry. The weight of this volume of hydrogen, at the temperature and pressure named, being taken as unity ($H=1$), that of a like volume of oxygen gas under the same conditions is approximately 16, or, more nearly, 15.96; that of nitrogen being 14, and

that of chlorine 35.5. If now we bring together, under these conditions of temperature and pressure, 2 litres of hydrogen and 1 litre of oxygen gas, no change takes place until by the intervention of flame or the electric spark, or more slowly by the action of spongy platinum, their union is effected, with dissipation of radiant energy. The product of the integration of the two gases may exist at 0° either as solid ice or as liquid water. This latter at 100°, overcoming the atmospheric pressure of 760 m.m., passes into water vapour, which at higher temperatures is subject to the common law governing the thermic expansion of gases, but at length reaches a point at which at standard pressure it undergoes heterogeneous disintegration, being resolved into its constituent gaseous elements. The weight of a litre of water vapour is the sum of the weights of a litre of hydrogen and half a litre of oxygen, the volume of the latter, as well as the specific characters of both, having in the act of integration been lost in that of a new species, so that the weight of a litre of hydrogen at 0° and 760 m.m. being unity = 1.00, that of a litre of water vapour reduced by calculation to the same standard temperature and pressure = 8.98. But as the combining weight for water vapour—or, in other words, its integral weight—is found to be twice that number, or 17.96, its volume is represented by 2 litres. It is thus, in the language of A. W. Hofmann, dilital. When, in the older notation, the volume of eight parts of oxygen was assumed as the unit, O=8, water vapour, then written, H₂O₂, was said to consist of four volumes of hydrogen and two of oxygen condensed into four volumes of vapour.

(To be continued).

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING SEPTEMBER 30TH, 1888.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolitan Water Act, 1871.

London, October 6th, 1888.

SIR,—We submit herewith the results of our analyses of the 175 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from September 1st to September 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

The analyses of the waters of the past month show them to have been of high quality, a manifest reduction in the dissolved organic matter being apparent. Thus, during August, the average oxygen required per gallon for the Thames-derived waters when examined by the oxygen process was 0.071 grain, whilst for September it was 0.043 grain. In like manner the organic carbon shows a reduction from 0.120 grain per gallon in August to 0.104 grain in September. The unusual meteorology of the Summer,

referred to in a previous report, has had its influence (as we should have expected) on the character of the waters. They have, however, throughout been of excellent quality.

Of 175 samples examined during September, 165 were found to be absolutely free from any trace of visible suspended matter.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

CORRESPONDENCE.

NOTE ON A NEW TEST FOR IRON.

To the Editor of the Chemical News.

SIR,—In the article appearing under this heading in this week's issue of the CHEMICAL NEWS (vol. lviii., p. 170), transcribed from the *Journal of Analytical Chemistry*, it is stated that the blue solution produced by the addition of strong hydrochloric acid to a cobalt salt becomes green in the presence of a trace of a ferric salt, of which 0.03 m.grm. can be thus detected.

I find that the presence of cobalt is needless, as the well-known yellow colour produced by the addition of strong hydrochloric acid to a ferric salt is quite distinct at this degree of dilution. Further, it is stated that the green colour is probably not due to the mere mixing of the blue and yellow solutions, for other yellow solutions fail to give the green. This I cannot endorse, as I obtained the green colour using such diverse yellows as platinum chloride and potassium bichromate.

I may mention that strong hydrochloric acid is an extremely delicate test for cobalt itself, I having detected a minute trace in a sample of tin by its means.—I am, &c.,

BERTRAM BLOUNT.

ANALYSIS OF FERTILISERS.

To the Editor of the Chemical News.

SIR,—I am at present working on the above subject, and as Mr. Firby (CHEMICAL NEWS, vol. lviii., p. 170) has drawn attention to the high results obtained in estimating phosphate of lime by the magnesia method, I would like now to give a few of my preliminary results on this branch of the investigation, instead of waiting until it is finished.

The dissolved manures which the experiments were carried out on were manufactured from Curacao, Aruba, Canadian, Carolina, and Belgian phosphates, bones, and a variety of ammoniated materials, and in all these cases my experience goes to show that either there is no silica soluble in hydrochloric acid or in water, or, what comes to much the same thing, it has no effect on the phosphate determination.

The experiments this is based upon are as follows:—

1. 50 grains pyrophosphate of magnesia, obtained from estimations of "soluble phosphate," was treated with hot dilute hydrochloric acid, boiled, the insoluble residue filtered off, washed, and ignited; it weighed 0.03 grain.

2. 110 grains obtained from estimations of "total phosphate" treated in same manner gave 0.15 grain insoluble residue.

When one remembers that there was some of the filter-ash left in the precipitates, these figures do not leave much room for silica, and no chemist will deny that if there had been any silica precipitated it would have become insoluble in dilute hydrochloric acid.

Fresenius points out ("Quantitative Analysis, 7th Ed., page 366) that it is not safe to evaporate a hydrochloric

acid solution of a phosphate to complete dryness, as pyrophosphoric acid is formed at temperatures below 150° C. Has Mr. Firby remembered this when he got a difference of $4\frac{1}{2}$ per cent?

It may be that in some rare cases there is soluble silica enough to give results so much above the truth, but I am perfectly satisfied it is not in a fertiliser made from any of the raw materials mentioned.

Mr. Firby's letter is apt to lead one to the conclusion that the majority of estimations of soluble and total phosphate are by far too high, and thus tells very sorely and unfairly against the manufacturer, as the above two experiments show—at least, so far as my firm's articles are concerned.—I am, &c.,

ALEX. BUCHAN, F.I.C.

Port Dundas Chemical Manure Works,
Glasgow, Oct. 11, 1888.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Moniteur Scientifique, Quesneville.

On Levulose.—A. Herzfeld.—From *Liebig's Annalen*.

On the Limited Sensitiveness of Indicators and on Some Qualitative Reactions.—E. Dietrich.—The author shows that for sulphuric and hydrochloric acids blue litmus, and still more blue alkanet, are more sensitive than tropeolin and Congo red. For potassa the most delicate reagents are red alkanet and logwood. For ammonia the same two reagents and rosolic acid take the first rank.

The Isomers of Tannic Acid.—Hugo Schiff.—From *Liebig's Annalen*.

The Proportion in which Chloride of Lime Loses its Active Chlorine if Kept at Different Temperatures.—John Pattinson.—From the *Journal of the Society of Chemical Industry*.

Recovery of Sulphur from Alkali Waste by Means of the Gases from Lime-kilns.—Alexander Chance.—From the *Journal of the Society of Chemical Industry*.

Saccharine or Coal-tar Sugar.—Ch. Girard.—Passages are quoted from Dr. Fahlberg, in which he evidently contemplates the use of saccharine as a means of enabling glucose to be passed off as cane-sugar. The important fact is mentioned that bees, flies, &c., refuse to taste saccharine, and even avoid it. A burlesque patent specification by a Dr. Fahlhrügel, of Reklamendorf (or, in English, "Puffingthorpe"), appears in a supplement to the *Berlin Berichte*. It is proposed to recover saccharine in great cities by collecting the excreta, extracting them with petroleum ether, and distilling off the liquid.

Report to the Prefect of Police on the Introduction of Saccharine into Alimentary Matters.—Dujardin Beaumetz.

Analysis of Nitrogen Chloride.—Dr. Gattermann.—The formula resulting from the author's analysis is NCl_3 . The compound may be violently exploded by the action of the sun or of the magnesium light, but it never explodes in darkness or on gloomy days.

Industrial Society of Mulhouse.—Session of April 11.—M. Paul Werner sent in a paper on the colouration of aniline if exposed to the air, which he finds is due to an absorption of oxygen under the influence of light.

Session of May 9.

A discussion took place on the priority of L. Schwartz as the inventor of garanceux, a matter which has no longer any practical interest.

Extraordinary Session, May 23.

M. Maurice Prud'homme sent in an account of a tartar emetic resist under tannin aniline steam-colours. This communication should have been made in July or September, 1881.

Session of June 13.

The Committee was engaged in revising the list of prizes to be offered.

The Compounds of Ammonia with Selenium Dioxide.—C. Cameron and J. Macallan.—From the *CHEMICAL NEWS*.

Iodide of Starch.—H. Stocks.—From the *CHEMICAL NEWS*.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 4.

Determination of Nitric Acid.—Dr. H. Wilfarth.—This memoir cannot be reproduced without the accompanying illustrations.

Determination of Sugar in Liqueurs, Confectionery, and Chocolate.—F. Rathgen.—The first test to be applied to a liqueur or an article of confectionery is to heat the aqueous solution with a little copper sulphate and soda-lye. If there is no precipitate of cuprous oxide, or but a slight one, we may polarise at once. In the presence of appreciable quantities of inverted sugar or glucose the inversion process of Clerget is recommended. Many kinds of confectionery require special procedures. The solutions must generally be decolourised with aluminium hydroxide and charred blood. In gum lozenges the sugar cannot be determined by a polaristrometric process, since the optically active gum cannot be completely separated by means of alcohol. In "caramels" an accurate determination of saccharose is not practicable, as glucose is present to the extent of about 16 per cent.

Determination of Sulphur in Cokes.—L. Blum.—Already noticed.

Determination of Fatty Matter in Linseed Cake.—R. Klopsch.—In a linseed cake containing 11 per cent of fat two successive analyses gave only 4.5 and 4.8 per cent. In searching for the cause the author found that prolonged desiccation with heat renders the fatty matter insoluble in ether. The author recommends that the drying process should not be prolonged beyond three hours.

Concluding Remarks on the Application of the Knop-Wolf Method in the Analysis of Soils.—Dr. A. Baumann.—The author recommends all chemists who are not yet convinced of the worthlessness of the Knop-Wolf process to apply it carefully and exactly, as prescribed by Knop, to three lots of soil, one of 200 to 300 grms., the quantity which Knop formerly used and recommended, one of 100 grms., which Knop now thinks the proper quantity for use, and one of 10 grms.

Qualitative Separation of Gold and Platinum from Arsenic, Antimony, and Tin.—Dr. L. de Koninck and Dr. A. Lecrenier.—Already inserted.

Determination of Carbon in the Irons of Commerce.—L. L. de Koninck.—Already inserted.

Determination of Fat in Milk and Cream.—Dr. Werner Schmid.—The author takes a test-tube of about 50 c.c. capacity, graduated in tenths of a c.c., introduces 5 c.c. of cream or 10 c.c. of milk, accurately measured, adds 10 c.c. of strong hydrochloric acid, boils, with shaking, until the liquid turns dark brown, cools by placing the tube in cold water, adds 30 c.c. of ether, shakes round, lets stand, measures the volume of the ethereal solution, draws off 10 c.c. with a pipette, evaporates down in a weighed porcelain capsule on the water-bath, and finally in an air-bath at 100°. He then weighs and calculates for the original quantity of the ethereal solution. If the process has been rightly conducted the ether separates from the aqueous solution clear, without the slightest turbidity. The ethereal solution, as it flows out of the pipette, should not show any watery drops. The results are perfectly accurate, and differ from each other and from the ordinary gravimetric methods by less than one-tenth per cent. The operation requires at most fifteen minutes.

An Aspirator with Constant Outflow.—Otto Binder.—This paper cannot be reproduced without the accompanying figures.

Safety-Retort for the Preparation of Gas.—N. von Klobulow.—This memoir also requires the accompanying illustration.

Molnar's Equally-working Suction Apparatus.—Von Klobulow.—The author shows that Molnar's apparatus is in principle identical with his own "Air-pump Regulator, described in *Zeit. f. Anal. Chem.*, xxiv., p. 399.

Two Measuring Instruments with Patent Cocks.—Greiner and Freidrichs.—Unintelligible without the three accompanying figures.

Official Proclamation on the Examination of Colours, Yarns, and Tissues for Arsenic and Tin.—An account of the methods for such investigations which are now legally compulsory in Germany. The processes given will be inserted as early as possible.

The Vapour-tension of Mercury.—W. Ramsay and Sidney Young.—From the *Journal of the Chemical Society*.

The Absorption of Watery Vapour from Moist Air by Solids.—T. Ihmori.—Metal coated with shellac varnish takes up much moisture, but little water is precipitated upon burnished metal. Oxidised metallic surfaces take up relatively much water and lose it again only partially in dry air. Rock crystal, if properly cleansed, takes up little water. Platinum, if cleansed with leather, absorbs no water. Hence the metallic parts of balances should be platinised wherever possible; the use of shellac varnish is very disadvantageous. The use of agate in the beams of balances should be avoided.

Simplification of the Calculation of Analyses.—E. A. Uehling.—The author proposes that as many grms. of the substance in question should be taken as the precipitate to be weighed contains per cents of the compound to be obtained.

On the Corrections of Analyses.—W. A. Dixon.—From the *CHEMICAL NEWS*.

The Incineration of Organic Matter.—Processes devised by Alex. Köbrich and H. Kronberg, and both taken from the *Chemiker Zeitung*. The Kronberg process is as follows:—In order to incinerate substances which, during incineration, swell up strongly like sugar or deflagrate slightly or give off dust like the salts of the organic nitro-acids, the author weighs off a portion of the pulverised sample in a glass tube which can be stoppered, and transfers it to the platinum crucible in such small portions that no tumefaction or dispersion of ashes can take place. The crucible contains, as a stirring-rod, a short thick straight platinum wire, which projects above

the edge of the crucible only so far that it may be grasped, passes through a very small lateral opening in the edge of the lid, and is weighed along with the crucible and lid. The charge is ignited, the crucible being covered, beginning at the side, and continuing to ignite with the crucible placed in a slanting position. The ash is crushed, if necessary, with the platinum rod, the crucible is let cool, and a further portion of the substance is added and treated as above. When a sufficient quantity of the ash has thus collected, the entire mass is ignited at a higher temperature. For the completion of the incineration, if nitric or sulphuric acid is inadmissible, the crucible is let cool down to about the boiling-point of water, and so much water is added drop by drop along the side of the crucible that on stirring with the wire all the soluble salts are dissolved. Any carbonaceous matter remaining is brought to the sides of the crucible, the small quantity of water is cautiously evaporated away, and the whole is re-ignited.

Incineration of Coke and Graphite.—Fr. Stolba (*Listy Chemické*) recommends the addition of silver powder, prepared by the reduction of silver chloride in the moist way. Finely ground graphite or coke is mixed with an equal weight of pulverulent silver and heated to redness in a platinum crucible. Fusion of the silver must be avoided. In this manner the combustion is very rapidly effected.

Viscosimeter.—S. M. Babcock.—From the *Journal of Analytical Chemistry*.

Influence of Organic Bodies upon Iodometric Determinations.—J. Klaudie (*Listy Chemické*).—Fatty acids and sugar have no effect. Aldehyds, phenols, gallic and tannic acids consume considerable quantities of sugar. This circumstance must be remembered in the examination of waste waters.

The Methods of the Mechanical Analysis of Soils.—T. B. Osborne.—From the *Journal of Analytical Chemistry*.

The Structure and Use of Scientific Balances.—G. Schwirkus, Th. Thiesen, and A. Springer.—These papers are merely mentioned.

Determination of the Specific Gravity of Large Solids.—O. Kleinstuck.—The author proposes as pyknometer a wide cylinder with a polished edge, closed with a glass plate, ground to fit.

International Areometer.—F. Spence.—From the *CHEMICAL NEWS*.

Prevention of the Regurgitation of Absorbent Liquids.—K. J. Bayer (*Chemiker Zeitung*).—For this purpose the author connects the generator with the absorbent vessel by means of a bulb-tube drawn out to a capillary at its exit end.

Apparatus for the Detection of Small Quantities of Carbonic Acid.—O. Rössler.

A Mill for Comminuting Minerals for Analysis.—K. Zulkowsky.—Both these papers require the accompanying figures.

Wanted, Second-hand Ironwork for Pyrites (lump) Burners—must be in good condition.—Address, with sketch, stating price, to Box 888, *CHEMICAL NEWS* Office, Boy Court, Ludgate Hill, London, E.C.

RUHMKORFF'S INDUCTION COIL
wanted. Must give at least 3-inch spark. Send full particulars, name of maker, and original price to Bernard Dyer, 17, Great Tower Street, London, E.C.

M R . J . S . M E R R Y ,
ASSAYER AND ANALYTICAL CHEMIST
SWANSEA

FOR SALE.—THE *CHEMICAL GAZETTE*.
Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," *CHEMICAL NEWS* Office, Boy Court, Ludgate Hill London, E.C

Now ready, Crown 8vo., cloth, 5s.

THE ANALYST'S LABORATORY COMPANION. By ALFRED E. JOHNSON, Assoc. R.C.Sc.I., F.I.C., F.C.S., First Prizeman in Chemistry, Physics, and Mathematics of the Royal College of Science for Ireland.

London: J. and A. CHURCHILL, 11, New Burlington Street.

This day, Crown 8vo., 7s. 6d. cloth (post free).

THE METALLURGY OF GOLD: A Practical Treatise on the Metallurgical Treatment of Gold-bearing Ores, including the Processes of Concentration and Chlorination, and the Assaying and Refining of Gold. By M. EISSLER, Mining Engineer, formerly Assistant Assayer of the U.S. Mint, San Francisco. With 90 Illustrations.

London: CROSBY LOCKWOOD and SON,
7, Stationers' Hall Court, E.C.

MINERALS.—On Sale, an Extensive Collection of Minerals, comprising over 900 Specimens, in splendid condition, classified in Cabinet; also a few good Freestone Fossils. For particulars, &c., apply to Robert Richardson, Southowram, near Halifax.

NAPHTHOL YELLOW.

NOTICE IS HEREBY GIVEN to Consumers, Dealers, and Manufacturers of "Naphthol Yellow" or "Fast Yellow" that such yellow colouring-matter is the subject of Letters Patent dated the 29th day of December, 1879, No. 5,305, which are the property of the Badische Anilin und Soda Fabrik, of Ludwigshafen-on-the-Rhine and Stuttgart, Germany.

The above mentioned colouring-matter can be purchased from the Badische Anilin und Soda Fabrik through their appointed Agents in Great Britain—

MESSRS. SCHOTT, SEGNER, & CO., 26, Princess Street, Manchester.

MESSRS. JAMES STRANG & SON, 30, Gordon Street, Glasgow.

MR. HENRY BECK, 22, Bush Lane, Cannon Street, London.

Or from their Licensees in England under the said patent,

MESSRS. I. LEVINSTEIN & CO., of Blackley and Crumpsall Vale Chemical Works, and 21, Minshall Street, Manchester.

Proceedings have been commenced in the Chancery Division of Her Majesty's High Court of Justice by the Badische Anilin und Soda Fabrik to restrain an infringement of this patent, and such proceedings are now pending.

The public and particularly Manufacturers and Consumers of Naphthol Yellow are cautioned that proceedings will be taken against anyone infringing the rights of the Badische Anilin und Soda Fabrik under the above mentioned patent.

J. H. JOHNSON, SON, & ELLIS,
47, Lincoln's Inn Fields, London,
Solicitors for the above named
Badische Anilin und Soda Fabrik.

WILLIAM FOX, ANALYTICAL CHEMIST,
LABORATORY:
4, GREAT TOWER STREET, LONDON. E.C.

EMPTY PETROLEUM BARRELS.

Empties may be delivered for our account to—

ATLANTIC WHARF, BOW COMMON,
WESTERN WHARF, OLD KENT ROAD,
Or THAMES HAVEN PETROLEUM WHARF, THAMES HAVEN.

WE ALSO RECEIVE EMPTIES AT THE VARIOUS LONDON RAILWAY DEPOTS

The same Price paid for Barrels branded with our own Brand, "LUSTRE," as for Barrels branded with American Brands.

NOTICE.—In the case of Empties sent for our account to Thame Haven Wharf or a Railway Depot, please advise us when sending, and mark K on the end of the barrels in Red Paint, that we may recognise them.

DEDUCTIONS FOR DAMAGE.—Broken Chimb or Stave 6d. Broken Head 6d. to 1s. 6d. according to extent of damage.

COMPANY'S STEAMERS:—

"ELBRUZ," 3700 Tons of Oil capacity.
"KASBEK," 3700 " " "
"ARARAT," 3700 " " "

SPECIAL NOTICE.—As our Oil would be seriously damaged if put into Barrels that have contained Paraffin Oil, Paraffin Empties are useless to us, and we are compelled therefore to decline to receive them.

THE KEROSENE COMPANY, LIMITED,

THE CHEMICAL NEWS.

VOL. LVIII. No. 1509.

ON A NEW MIXTURE FOR SEPARATING CARBON FROM PIG-IRON, STEEL, &c.

By T. W. HOGG.

THE most accurate methods that have been proposed for the determination of carbon in steel, pig-iron, and other ferro-carbon alloys, are those in which the carbon is first separated in a state of proximate purity, and afterwards burnt in a current of oxygen.

In order that this separation may be effected it is simply necessary to treat the particular ferro-carbon alloy with some salt whose base can either be substituted entirely, or where the salt can be reduced to some lower compound by the iron present in the alloy; the carbon not taking any part in the reaction is left behind as such, and may be filtered off for further treatment.

It is obvious that quite a considerable number of salts are capable of effecting this separation, and a great many have been recommended for the purpose, but none of them have given such general satisfaction as a neutral solution of cupric chloride. However, even this cupric chloride possesses one objectionable quality,—the decomposition of the alloy is accompanied by the production of cuprous chloride, and, as this is comparatively speaking an insoluble compound, it is necessary to provide against its precipitation: this is accomplished by adding an abundance of concentrated hydrochloric acid, or by having present in great excess a saturated solution of some salt such as sodium or ammoniac chloride.

Whatever plan may be adopted, this insolubility of the cuprous chloride is always troublesome, and occasionally proves an intolerable nuisance; and it is the object of this short paper to draw attention to a reaction familiar to every chemist by means of which this inconvenience may be entirely removed.

When a solution of ferric chloride is added to cuprous chloride an immediate change takes place, cupric chloride and ferrous chloride being formed.

The ferric chloride solution may be utilised in different ways by the operator; he may conduct the analysis by means of cupric chloride as usual, and at the end decompose the cuprous chloride by adding sufficient ferric chloride, or he may add this salt as soon as the mixture of metallic copper and carbon is obtained. A little gentle heating, aided by a few drops of hydrochloric acid, will suffice to cause the whole of the metallic copper to be dissolved by the ferric chloride.

The ferric chloride may be used in a still more advantageous and economical point of view; it will itself, as is well known, decompose most ferro-carbon alloys, but not without some loss of carbon; but if a small proportion of cupric chloride be present this loss is entirely prevented. The decomposition proceeds entirely through the medium of the copper salt, which is at first reduced and then reformed at the expense of the ferric chloride.

The ferric chloride should possess a sp. gr. of about 1.30, and the copper salt 1.35, but so long as these solutions are kept pretty concentrated the exact strength is not a matter of very great consequence; a little ammonium hydrate should be added to neutralise any excess of free acid that might be present. The ferric chloride will dissolve ferric hydrate long after all free acid is neutralised, so that it is best to try the mixture with a high carbon steel, and ascertain whether there is any indication of the evolution of hydrocarbons.

After weighing the requisite quantity of the alloy, and placing it in a beaker, sufficient cupric chloride is added to cover the borings to the depth of about half an inch, and then a considerable excess of the ferric chloride solution is added; after about five minutes' stirring the beaker is placed upon a lamp and heated gently up to boiling-point, and if the borings have been in the proper state of fineness the decomposition will be completed within twenty minutes, and, after adding a few drops of hydrochloric acid, to prevent the precipitation of basic compounds, the carbonaceous residue may be filtered off, and washed prior to further treatment.

In dealing with alloys containing silicon up to about 4 per cent, the carbon should always be filtered off as soon as the alloy is quite decomposed; it is a common occurrence to allow the borings and the cupric chloride to stand all night, and, if this is done, the silicic acid which results from the oxidation of the silicon, and which at first passes almost entirely into solution, is often partially precipitated in the gelatinous condition, with the result that the filtration becomes very tedious.

Newburn Steel-Works,
near Newcastle-on-Tyne.

ON A CERIUM SALT OF CHINOLINE.

By GREVILLE WILLIAMS, F.R.S.

I HAVE shown in my "Researches on Chinoline and its Homologues,"* and "Researches on Isomeric Alkaloids,"† that β -lutidine and chinoline form double salts with gold, copper, cadmium, uranium, platinum, and palladium, and I find that they do so with some of the metals of the cerite earths. Didymous sulphate forms a double salt with β -lutidine, but I have not yet succeeded in obtaining the corresponding lanthanous salt. The didymium salt is not easily prepared in a state of purity. The most beautiful double salt of the cerite earths that I have seen is that formed with nitrate of chinoline and ceric nitrate. On mixing moderately concentrated solutions of the two salts, glittering orange-red rhombic plates of the double nitrate of cerium and chinoline form at once. The salt may be obtained in superb crystals by slow evaporation of a dilute solution. The alkaloid from cinchonine, and that prepared synthetically by Skraup's process, give products similar in appearance. The air-dried salt is anhydrous. The ceric nitrate used was prepared from oxide which had been separated from lanthana and didymia by fusion with nitre. On heating the double salt it fuses readily, giving off red fumes and a powerful odour of nitrobenzol. This last fact is interesting, and reminds us of Dewar's transformation of chinoline into aniline. Great care has to be taken in determining the ceric oxide by ignition of the double salt, as it is liable to deflagrate; and it is better to mix the salt previously with a known weight of sulphate of barium or silica. Even with this precaution I have met with considerable variations in the estimations. The following numbers were obtained on analysis.

I.	0.2955 grm.	gave 0.0654 grm. ceric oxide.
II.	0.5547 "	0.1257 " "
III.	0.4581 "	0.1050 " "
IV.	0.5972 "	0.1364 " "
V.	0.5145 "	0.5288 CO ₂ and 0.1040 H ₂ O.

or, per cent—

The ceric oxide obtained in the above determinations was always of a rich orange colour when hot, and yellow with a faint apricot tint when cold.

A CRYSTALLINE SUBSULPHIDE OF IRON AND NICKEL.

By J. B. MACKINTOSH,
Lehigh University, South Bethlehem, Pa.

SOME months ago I received a sample of a highly crystalline product occurring in the hearth of the shaft-furnace used in smelting the roasted nicoliferous pyrrhotite at Mr. Joseph Wharton's Works, near the Gap Mine, Lancaster County, Pa.

Mr. Wharton first observed this product in cavities in the concretions in these furnaces about the year 1870, and published a description of it in that year.* Thinking that it might show some analogy to meteoric iron he sent the present sample to Mr. George F. Kunz, who turned it over to me, with the request that I should analyse it at my convenience. The results do not show the expected analogy, because the sulphur in meteoric iron is combined as FeS, while in this product there is only one-sixth the necessary amount of sulphur, which, however, seems to be combined with all the metallic elements present, forming a subsulphide of definite composition. I am informed by Mr. Wharton that he has had for a long time the sample which I have analysed, and that it probably is about the same age as that which he first described. It is worthy of note that the material does not show any signs of oxidation, but that the crystals preserve a brilliant metallic lustre.

The first two analyses, made by Mr. J. Voigt, are those given by Mr. Wharton in his paper above referred to; the third is the analysis I have just completed.

	Voigt. Octahedral crystals.	Granular mass.	Mackintosh. Cubical crystals.
Cu	1.85	1.74	2.20
Ni, Co ..	25.22	28.20	26.16

Theoretical for Fe₄Ni₃S.

Ni	31.29
Fe	60.12
S	8.59

100.00

In my analysis there is a small amount of silica which is present in mechanical admixture, in the form of slag or furnace-lining. The deficiency in the analysis is due to the other constituents of this admixture. In the granular mass the sulphur is deficient; but as it was a granular mass, on which the octahedral crystals were imbedded, it could not be expected to be a definite compound. In the case of the other two analyses, however, both made on crystalline material of approximate purity, the results are

quite accordant, and agree with a compound of the general formula R₆S. The ratio of the metals is, roughly, two of iron to one of nickel and copper, and it will be seen, from the theoretical composition which I have calculated on that assumption, that the results of analysis do not vary very much from those calculated.

From a chemical standpoint this compound is of great interest, as it distinctly illustrates the hexatomic character of sulphur, and to the best of my belief is the only known sulphide of similar composition. The manner of occurrence is in small cubical crystals, forming fern-like aggregations, in the cavities in the concretions in the furnace-hearth.

I think it is quite probable that analogous compounds will be formed in copper-smelting; and I would be pleased to receive samples of any similar product from anyone whose attention may be directed to this note.—*Transactions of the American Institute of Mining Engineers.*

REPORT OF THE COMMITTEE ON INDEXING CHEMICAL LITERATURE.*

THE Committee on Indexing Chemical Literature respectfully present to the Chemical Section its Sixth Annual Report.

By the liberality of the Association the Committee secured 500 copies of the Report for 1887, and these were distributed through the Secretaries of the American Chemical Society, the London Chemical Society, and the Washington Chemical Society, and directly by the Chairman of the Committee. The Provisional List of Abbreviations of Titles of Chemical Journals which formed Appendix B to the Report was received by chemists with general approbation, and was reprinted in the *Proceedings of the American Association for the Advancement of Science*, *CHEMICAL NEWS* (London), *American Chemical Journal* (Baltimore), *Journal of Analytical Chemistry* (Easton), *Journal of the American Chemical Society* (New York), and was favourably noticed in the *American Journal of Science* (New Haven): this practically ensures its adoption.

During the year just closed the "Index to the Literature of the Spectroscope," by Dr. Alfred Tuckerman, has been published by the Smithsonian Institution. This forms a work of about 400 pages, and contains 3829 titles by 799 authors.

"The Table of Specific Gravities for Solids and Liquids," by Prof. F. W. Clarke, is now in the compositor's hands, and will soon be published by the Smithsonian Institution. This work is really a new and completely revised edition of Part I. of the original "Constants of Nature."

An "Index to the Literature of Columbium," by Prof. Frank W. Traphagen, has been completed and accepted by the Committee, who recommend its publication by the Smithsonian Institution.

Dr. H. C. Bolton has compiled a "Bibliography of Chemistry for 1887," which is also in the hands of the Smithsonian Institution.

Several chemists project indexes, and have made more or less progress on them. Mr. Arthur A. Noyes is engaged on an Index to the Literature of Ethylene; Prof. William P. Mason volunteers to index Methane; Mr. William Rupp undertakes to index Cæsium and Rubidium; Prof. Traphagen plans to index Tantalum; Dr. H. C. Bolton has in preparation a "Bibliography of the History of Chemistry, including Biography and Bibliography"; and Dr. Alfred Tuckerman is engaged in indexing the literature to Thermo-dynamics.

Several bibliographies merit brief mention: Dr. Jesse P. Battershall's "Food Adulteration and its Detection"

* *American Journal of Science*, vol. xlix., p. 365, "On Two Peculiar Products in the Nickel Manufacture."

* From advance sheets of *Proceedings of the American Association for the Advancement of Science*, Cleveland Meeting, August, 1888.

(New York, 1887) contains an Appendix with the title—"Bibliography including Periodicals, Reports, and General Works chronologically arranged." This includes about 275 titles. The "Second Annual Report of the N. Y. State Dairy Commissioner" (1886) contains a Bibliography of Milk, by Mr. Edward W. Martin (pp. 156 to 170), and a Bibliography of Butter, adulterations, testing, &c., by Prof. Elwyn Waller, assisted by E. W. Martin and others (pp. 283 to 290).

Brof. Wm. H. Seaman calls the attention of the Committee to several lists of United States Patents which relate more or less to applied chemistry. These lists on subjects indicated by their titles are found in the following works:—Charles Thomas Davis, "Manufacture of Leather"; the same, "Practical Treatise on the Manufacture of Bricks, Tiles, and Terra Cotta"; the same, "Treatise on Steam Boiler Incrustations"; the same, "Practical Treatise on the Manufacture of Paper"; Wm. T. Brannt, "Treatise on Animal and Vegetable Fats and Oils." These are all published in Philadelphia, 1884 to 1887.

B. Tollens's "Handbuch der Kohlenhydrate" (Breslau, 1888) contains about 1500 references to the literature of carbohydrates.

Dr. Albert Brown Lyons publishes, in the *Pharmaceutical Era*, under the title "Index Pharmaceuticus," a monthly list of books on pharmacy, chemistry, and materia medica, as well as a list of original papers on these topics published in journals.

At the meeting of the British Association for the Advancement of Science held in 1886 a Committee was appointed for the purpose of reporting on the Bibliography of Solution. This Committee consists of Profs. Tilden, McLeod, Pickering, Ramsay, Young, A. R. Leeds, and Nicol (secretary), and presented its first report in 1887. This report sets forth the classification adopted, the list of journals (thirty-four in number) desirable to index, and a summary of work accomplished. From this summary it appears that 355 titles have been catalogued from 588 volumes of eleven different periodicals.

The Committee of the B. A. recommend to members of the Committee other gentlemen who have access to the journals on the list, and who would be willing to take an active share in the work.

The Committee of the American Association expresses its gratification that the work begun by them in 1882 is now being supplemented by chemists in England.

Persons desiring copies of reports, indexes, and other information, should address the Chairman, care of the Smithsonian Institution, Washington.

H. CARRINGTON BOLTON, *Chairman*.
F. W. CLARKE.
ALBERT R. LEEDS.
ALEXIS A. JULIEN.
JOHN W. LANGLEY.
SAMUEL H. SCUDDER.
CHAS. K. WEAD.

AUSTRALASIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE formation of the Association was first suggested by Prof. Liversidge, of the Sydney University, during the Exhibition in Sydney in 1879, but matters at that time not being considered quite ripe for it, the formation of the Association was again brought forward through the press in the year 1884. It was then suggested that, as it was unlikely the British Association would see its way to visit Australasia during the centennial year, an Australasian Association should be formed on the same lines as the parent Association, in order to bring about a federation or union of the members of the various scientific societies throughout Australasia.

It was also suggested that the First General Meeting should be held in Sydney on the One Hundredth Anniversary of the Foundation of the Colony, as it was at that time thought there would be an International Exhibition in Sydney to celebrate that event.

In furtherance of the project a preliminary meeting of Delegates from various scientific societies was held in Sydney in 1886 (November), the project having thus early met with the approbation and support of the majority of the learned and scientific societies of Australasia.

At this meeting the formation of the Australasian Association for the Advancement of Science was agreed to unanimously, the Rules of the British Association being adopted until the First General Meeting, which it was decided should be held in Sydney during 1888, the Centennial Year.

In accordance with another resolution passed at the meeting of Delegates, the election of officers for the year 1888 took place in Sydney in March of the present year:—Mr. H. C. Russell, B.A., F.R.S., Government Astronomer of New South Wales, being elected President, Sir Edward Strickland, K.C.B., F.R.G.S., Hon. Treasurer, and Prof. Liversidge, M.A., F.R.S., and Dr. George Bennett, F.L.S., Hon. Secretaries.

The formation of the General Council was afterwards proceeded with, each society electing one representative for every hundred of its members, and the Chief Justice and Minister for Public Instruction of New South Wales, the Chancellor and Vice-Chancellor of the Sydney University, the Mayor of Sydney, and the Presidents of the Royal Societies of the various colonies were elected Vice-Presidents for the year.

The Presidents of Sections were then elected, the gentlemen chosen being all resident in other colonies than New South Wales, whilst the Secretaries of Sections, as a matter of necessity, were elected from amongst residents in Sydney.

In all about 8000 invitations to join the Association were sent out to members of the various learned and scientific societies, professions, &c., and practically every society coming within the scope of the Association has one or more representative on the General Council.

The Association is thoroughly Australasian in its character and members, and the succeeding General Meetings are to take place in turn in the capitals of the other colonies, the executive officers being elected year by year by the colony in which the meeting is held. It has been decided, however, that Sydney shall be the permanent headquarters of the Association, and that Professor Liversidge shall be the permanent Hon. Secretary.

The First General Meeting was held at Sydney University, the opening ceremony, at which His Excellency the Governor delivered a speech, taking place on Tuesday evening, August 28, when the Presidential Address was delivered.

On the following day the Sectional Meetings commenced, and all the Sections, with one exception, brought their proceedings to a close with the end of the week.

About 110 papers were sent in by gentlemen of distinction in the various branches of science, literature, and art in the different colonies, and a considerable number of the papers are to be published in full in the first volume soon to be issued by the Association.

It may, therefore, be anticipated that the work done by the Association during the first year of its existence is of a highly important and useful character.

The more solid work of the meeting was lightened by excursions to various places of interest to geologists, botanists; and others, and every effort was made to provide for the entertainment and comfort of visiting members, numerous entertainments being given by leading citizens.

The various steamship companies arranged to convey members proceeding to Sydney to attend the meeting at a reduction of 20 per cent in the ordinary rates, and the Government Railway authorities of New South Wales,

Victoria, and South Australia issued return tickets at single rates.

A considerable number of members attended the meeting, and included amongst the visiting members were the leading scientific representatives of each colony.

It has been decided that the next meeting shall be held in Melbourne, and Baron Sir Ferdinand von Müller, the Government Botanist of Victoria, is the President elect for the year. In 1890 the Association is to meet in New Zealand.

The rules, as already mentioned, are practically the same as those of the British Association, and at the time of the meeting the new Association numbered about 850 members. It is confidently anticipated that this number will be considerably augmented, if not actually doubled, by the time the next General Meeting is held.

THE ESTIMATION OF QUININE BY KERNER'S METHOD.

By EDSSEL A. RUDDIMAN.

WITHIN the past few years unusual attention has been given to the examination of the sulphate of quinine for the other alkaloids which occur with it in cinchona barks, more especially cinchonidine. In this examination the method of Dr. Kerner, first published in 1862, has been adopted by the pharmacopœias of Germany, France, and the United States. The pharmacopœia of Great Britain adopts the first principle of Kerner's test—the removal of the excess of quinine by its crystallisation as sulphate—and then resorts to separation of free alkaloids by ether. Notwithstanding the general and official use of Kerner's operation to fix the quality of a medicinal agent of the first importance, this method is still open to questions of criticism, questions to be answered only by a course of investigation. The work undertaken by the writer has been devoted to determinations as follows:—

(1) As to the effect of an initial digestion of the medicinal sulphate of quinine in water at 100° C., followed by the digestion at 15° C., in comparison with results obtained by digesting at once at 15° C.

(2) As to the effect of variations in the temperature of the liquid during titration on the amount of ammonia necessary to re-dissolve the precipitate, filtration being always done at 15° C.

(3) As to the accuracy of Kerner's figures for the amount of ammonia water, sp. gr. 0.920, required to dissolve one m.grm. of cinchonidine sulphate.

(4) A proposed modification of the method for the quantitative estimation of cinchonidine sulphate in quinine sulphate.

(5) On the amount of water which should be taken in applying Kerner's test to salts of quinine other than the sulphate.

(1) *The Effect of Digesting Medicinal Quinine Sulphate at Different Temperatures.*—In an article published in 1877, Paul* called attention to the fact that, in the application of Kerner's test for the detection of cinchonidine sulphate in quinine sulphate, all of the cinchonidine is not dissolved. Since then, and more especially within the last few months, several writers as Paul†, Yungfleisch‡, the committee for the revision of the French Codex,§ Hesse,|| Kerner,¶ and others have acknowledged that there is truth in this statement. The reason given is that, in the manufacture the sulphates of quinine and cinchonidine

crystallise together. The amount of water of digestion being insufficient to dissolve all of the quinine, the cinchonidine is not all dissolved. The French Codex now directs that the digestion take place in hot water, while Yungfleisch advises that the temperature of the water used be 100° C. This undoubtedly makes the test far more severe, but even at 100° C. there is an insufficient amount of water to dissolve all of the quinine.

In testing the commercial salt I have made a modification of the U.S. Ph. method, and in so doing have attempted to make it such that, on an average, those samples of quinine which are included by the official test will be included by this modification, and those samples which are excluded by the official test will be excluded by this modification. It is as follows:—Take one grm. of the salt and dissolve in 30 c.c. of boiling water (this being enough to dissolve it), cool and digest at 15° C. for two hours, and filter. To 5.26 c.c.* of the filtrate add 7 c.c. of water of ammonia, sp. gr. 0.960, and a clear solution should be obtained. To determine the amount of filtrate which should be taken, I proceeded as follows:—One grm. of the salt was digested with 10 c.c. of water at 15° for three hours and filtered. To five c.c. of the filtrate, ammonia water, sp. gr. 0.960, was added from a burette until the precipitate was just re-dissolved and the amount† used was noted. One grm. of the same sample was dissolved in 30 c.c. of boiling water, the solution cooled, digested at 15° C. for three hours, and filtered. To five c.c. of the filtrate, ammonia was added as before and the amount used was noted. From these figures the required amount of filtrate of the sample digested at 100° C. may be calculated.‡ Twelve experiments as follows were made with samples of quinine from three manufacturers. Experiments I., II., and III. were made upon the same sample; experiments IV., V., and VI. on a sample from a different manufacturer; experiments VII., VIII., and IX. on one sample, and X., XI., and XII. on another sample from a third manufacturer.

	No. of expt.	No. of c.c. of ammonia required for 5 c.c. of filtrate after digesting 1 grm. of the salt in 10 c.c. of water at 15° C.	No. of c.c. of ammonia required for 5 c.c. of filtrate after digesting 1 grm. of the salt in 30 c.c. of water at 100° C.	Proportion
I.	7.1	8.8	8.8	8.8 : 7.1 :: 5 : x = 4.03
II.	7.2	9.4	9.4	9.4 : 7.2 :: 5 : x = 3.83
III.	6.6	7.9	7.9	7.9 : 6.6 :: 5 : x = 4.19
IV.	8.9	8.5	8.5	8.5 : 8.9 :: 5 : x = 5.23
V.	9.5	9.1	9.1	9.1 : 9.5 :: 5 : x = 5.21
VI.	9.5	9.05	9.05	9.05 : 9.5 :: 5 : x = 5.24
VII.	12.2	8.5	8.5	8.5 : 12.2 :: 5 : x = 7.17
VIII.	10.9	7.9	7.9	7.9 : 10.9 :: 5 : x = 6.89
IX.	11.3	8.2	8.2	8.2 : 11.3 :: 5 : x = 6.90
X.	7.5	7.9	7.9	7.9 : 7.5 :: 5 : x = 4.74
XI.	7.6	7.8	7.8	7.8 : 7.6 :: 5 : x = 4.87
XII.	7.4	7.5	7.5	7.5 : 7.4 :: 5 : x = 4.93

I found the average result of these twelve experiments to be 5.26 c.c. This figure may, however, be varied by further experiment, and in fact the amount varies for each sample. The variation depends upon the condition in which the cinchonidine sulphate exists. It may be deposited largely on the outside of the crystals of quinine sulphate, due to the incomplete separation of the mother liquor, in which case it may be easily dissolved; or it may be crystallised throughout with the quinine sulphate.

* Or, what is equivalent, 5 c.c. of the filtrate may be taken, and 6.65 c.c. of water of ammonia added.

† If the temperature of the resulting solution was above or below 15° C. due allowance was made.

‡ The proportion is: The amount of ammonia used for the 5 c.c. filtrate from sample digested at 100°: amount of ammonia used for 5 c.c. filtrate from sample digested at 15° :: 5 : x.

(2) *The Effect of the Temperature of Titration upon the Amount of Ammonia Taken.*—In applying the U.S. Ph. test to a sample of quinine sulphate, I observed that portions of the same filtrate indicated that the salt should be included or excluded by the test according to the temperature of the liquid after filtration. On having the temperature of the room such that the resulting mixture should be very nearly at 15° C., a distinct turbidity was formed on adding seven c.c. of water of ammonia (sp. gr. 0.960) to five c.c. of the filtrate, while if the temperature of the titrated liquid rose to about 25° C., a clear solution followed. To determine the exact effect of the temperature during titration upon the amount of ammonia required, I proceeded as follows:—The standard quinine sulphate* was prepared from Böhringer's quinine sulphate by adding the calculated amount of sulphuric acid necessary to convert it into the bisulphate, which was dissolved in hot water nearly to saturation and cooled. The crystals were then drained and dried by means of bibulous paper and a press. They were dissolved a second time and dried in a similar manner. The quinine bisulphate was then converted into the normal sulphate by adding a solution of sodium hydrate to neutralisation.

The crystals were twice dissolved in hot water, cooled, dried between filter paper and a third time dissolved in hot water, cooled, and allowed to effloresce.† The solution was made by digesting the standard quinine sulphate in water at the ordinary temperature, then reducing it to 15° C. for two hours, and filtering at the same temperature.

* Various methods for the purification of quinine sulphate have been given. See Kerner, *Zeitsch. Anal. Chem.*, xx., 150; Prescott, *Pro. Am. Pharm. Assoc.*, 1878, p. 828; Davies, *Pharm. Jour. Trans.* [3], xvi., 358; Hesse, *Pharm. Jour. Trans.* [3], xvi., 818.

† In all my experiments where standard quinine sulphate was used it was prepared in the same manner.

The ammonia solution was standardised* by titrating it with a normal solution of oxalic acid, using the table of percentage and specific gravity given in the U.S. Ph., 1880.

Regulating the temperature of the room so that it was near the temperature at which I wished to titrate, I proceeded as follows:—10 c.c. of the standard quinine sulphate solution were measured into a small globe-shaped flask by means of a pipette, and ammonia water was added from a burette to within one c.c. of the quantity required to dissolve the precipitate first formed. The flask was then closed with a stopper and inverted once. More ammonia was added, a few drops at a time, and afterwards drop by drop. After each addition the flask was closed, inverted, and allowed to stand a few seconds, taking for the whole titration four to five minutes. Immediately after the precipitate was re-dissolved the temperature of the solution was taken. Bringing together all the titrations made at the same degree of temperature, about ten titrations having been made for each degree, I found the average titre of ammonia for each degree between 14° and 26° C. inclusive, as given in the table below. The extremes of temperature, 14° and 26°, were chosen, since they are about the limits of ordinary temperature. Finding the difference of titre between each degree and the one next above it, I took the average of these differences to represent in general the decrease of ammonia required for the increase of each degree of the

* In all cases where ammonia was used it was standardised by titrating with oxalic acid. For sp. gr. 0.920 ammonia percentage 21.8 was used; for sp. gr. 0.960 percentage 9.8 was employed. These data are from the table of Carius, U.S. Ph., p. 425. According to the observations of A. B. Lyons, *Proc. Mich. Pharm. Assoc.*, p. 189, the 21.8 per cent corresponds to sp. gr. 0.92119; and the 9.8 per cent corresponds to 0.96170 (water at 40° C.=1, and temp. obs. 150° C.).

General average of differences for one degree=0.172 c.c.*

* It appears that of ammonia water of sp. gr. 0.960, there are required only 1.5 times more than of the water of sp. gr. 0.920, though the latter is 2.2 times stronger than the former.

centigrade thermometer. When ammonia water of sp. gr. 0.920 is used, the general average of all the differences is found to be 0.148 c.c., but for ammonia water sp. gr. 0.960 the general average is 0.172 c.c.

Then to obtain the correct amount of ammonia water, sp. gr. 0.920, necessary to re-dissolve the precipitate at 15° C., there must be added to the amount of ammonia used 0.148 c.c. for every degree of increase of temperature of titration. If ammonia water of sp. gr. 0.960 be used, then 0.172 c.c. must be added for every degree.

(To be continued).

THE FOUNDATIONS OF CHEMISTRY.*

By T. STERRY HUNT, LL.D., F.R.S.

(Continued from p. 195.)

8. THE condensation which appears in the union of hydrogen and oxygen gases to form water vapour has been defined as inter-penetration, but is more properly an identification of volume, or, to use Herbert Spencer's term, an integration of the two combining gases. When, however, a litre of hydrogen is mingled within a litre of chlorine gas at the standard temperature and pressure, the two unite with violence by the action of sunlight, of flame, or the electric spark, and form two litres of chlorhydric acid gas; the first action of light, according to recent observations of Pringsheim, producing a sudden and transient increase of volume (due perhaps to a disintegration of the chlorine, which marks a stage in the chemical process).† The properties of the combining gases are lost in those of the new compound, but, contrary to the general law of chemical union, in which integration is attended by condensation, there is no loss of volume. We have in this case for the weight of a litre of the newly formed gas, not the sum of the weight of a litre of hydrogen and a litre of chlorine, but one half of that sum, or 18.25 times that of the litre of hydrogen.

Further light is shown upon this process by the history of the related fluorhydric acid gas, which at and near 100° has a density corresponding to HF. At about 19°, however, it is reduced to a liquid at the ordinary pressure, and between 20° and 30° yields, according to Mallet, a gas or vapour corresponding to H₂F₂, which by a slight elevation of temperature is readily transformed into 2HF. This gaseous compound of greater density is what in accordance with the general law of chemical integration should be formed by the union of H₂ with F₂, and we may conclude that in the case of chlorhydric acid a similar compound, H₂Cl₂, is possible, which, however, would at once pass, at the ordinary temperature and pressure, into 2HCl.

9. The capacity of the compound of fluorine and hydrogen to exist at the ordinary pressure in two gaseous states of unlike density serves to illustrate many similar facts in the history of elemental and compound species alike. Among the latter are the well-known examples of acetic aldehyde, acetylene, pentene, and the various polymers of these. Among the elements, oxygen when liberated in the decomposition of water by fluorine (Moissan), or by electrolysis, appears in part in the gaseous modification known as ozone, having a density one and a half times that of the ordinary form of oxygen—that is to say, its weight is not sixteen times but twenty-four times that of hydrogen at the same temperature and pressure. The effect of the electric spark, and of the

silent electric discharge, to convert a considerable portion of dry oxygen into ozone, which is, however, rapidly resolved by heat, and more slowly at ordinary temperatures into common oxygen, 2O₃=3O₂; the case of selenium, which yields a condensed vapour, Se₃, resolvable at a higher temperature into Se₂; and that of the triply condensed sulphur vapour, S₆, now found to be convertible at higher temperature into S₂, corresponding to the normal oxygen, O₂; the vapours of phosphorus and arsenic, represented by P₄ and As₄, partially changed by heat into P₂ and As₂; and finally, the vapours of bromine and iodine, Br₂ and I₂, which alike by heat and by the explosive and silent electric discharge are more or less completely changed into unstable vapours of Br₁ and I₁—are all illustrations, then unknown, of the same principle of greater or less gaseous condensation, first advanced from theoretical considerations by the present writer in 1848 (§§2, 3). The fact that the silent electric discharge at a low temperature effects a similar disintegration in the vapours of bromine and iodine to that wrought by great heat or by the electric spark, thus producing a change apparently the reverse of that produced by the same silent discharge in oxygen gas, leads to the suggestion that the generation of ozone thereby may be due to the momentary disintegration of a portion of oxygen, O₂, into 2O, which at low temperatures unites with an unchanged portion to form O₃.

The examples above given will suffice to show that the principle of chemical change by integration and disintegration appears not only in the relations of unlike species with each other, as of hydrogen with oxygen, with fluorine, with chlorine, or with sulphur and iodine vapours, but also with these same simple gaseous species among themselves. In other words, the more elemental gaseous forms of oxygen, of sulphur, of iodine, of fluorhydric acid, and of hydrocarbonaceous bodies, unite with themselves by homogeneous integration to form new gaseous species differing in specific gravity and in other physical characters, which have been designated allotropic or polymeric forms. Thus the same principle applies alike to the union of similar and dissimilar species, to homogeneous and heterogeneous integration, or, in the language long since adopted by the writer, to *chemical metamorphosis* as well as to *chemical metagenesis*.

10. We have seen that while the unit of weight is represented by the litre of hydrogen at 0° and 760 m.m., the unit of combination for the derived species, such as water vapour and chlorhydric acid gas, is represented by twice this volume, the species being, in the language of Hofmann, dilital. The corresponding dilital volume of hydrogen gas itself then becomes H₂=2, a fact which is indicated by applying to it the term diad or diatomic. To this type of condensation also belongs nitrogen gas, together with oxygen, chlorine, and the vapours of bromine and iodine in their ordinary conditions, that of sulphur above 800° and of selenium above 1200°, that of tellurium, and probably that of antimony. Oxygen in the form of ozone, and selenium at low temperature, are triad or triatomic, while the ordinary vapours of phosphorus and arsenic are tetrad, apparently becoming diad at higher temperatures, and that of sulphur below 550° is hexad. Iodine vapour, as we have seen, may be metamorphosed into a monad species, in which its weight is not 127 times that of hydrogen gas at the same temperature, but one-half that number; while the vapours of mercury and cadmium are known only in a monad form. A similar metamorphosis by expansion or homogeneous disintegration is, from analogy, possible for hydrogen at elevated temperature and reduced pressure; that is to say, the production of a monad form of hydrogen, H, corresponding to monad cadmium vapour, Cd, and monad iodine vapour, I, and having for a litre at 0° and 760 m.m. a weight of 0.0448 grm. Nor can we assign any reason *a priori* why the process of homogeneous disintegration may not go on still further, unless indeed it be limited by a process of heterogeneous disintegration which may resolve the

* Read before the National Academy of Sciences, April 17, 1888. Reprinted from the *American Chemical Journal*, vol. x., No. 5.
† Pringsheim, L. E. D. *Philos. Magazine*, Dec., 1887, from *Wiedemann's Annal.* for Nov., 1887. The writer had already suggested that "the power of flame, or the electric spark, to effect the sudden union of chlorine and of oxygen with hydrogen, may be due to the effect of intense heat in separating momentarily into simpler forms portions of these gases, &c." ("A New Basis for Chemistry," § 57).

hydrogen into two or more unlike species, as supposed by Grünewald to be the case in the solar chromatosphere.

11. The weight of a litre of water vapour is made up of that of a litre of diad hydrogen, H_2 , with that of half a litre of diad oxygen; while the weight of a litre of chlorhydric acid gas includes only that of half a litre each of diad hydrogen and diad chlorine, or of a litre of monad hydrogen integrated with a litre of monad chlorine. Reasoning from compounds like this, it has been assumed that the weight of monad hydrogen, 0.0448 grm. to the litre of standard temperature and pressure, is the smallest admissible, and that the weight of the element in a litre of any compound vapour or gas must be a multiple of this by some whole number; that of oxygen, if present, being in like manner not less than 7.98 times this same weight. The question arises whether we have as yet any experimental evidence of such homogeneous disintegration as should give in the litre of any vapour or gas at 0° and 760 m.m. quantities of hydrogen or of oxygen not in accordance with these weights. In the vapour of ordinary water, in which the ratio by volume of $H : O = 100 : 50$, it is evident that there is no deviation from these values; but if, admitting the existence of an oxygenised water as described by Schützenberger, in which that ratio is $100 : 51$ ($1.0 : 8.14$ by weight), we suppose this to be converted into a homogeneous vapour containing in a litre 0.0896 grm. of hydrogen, it is evident that the oxygen, being not 0.0896×7.98 but 0.0896×8.14 , will be equal to one and one-fiftieth portions. Further evidence of the distinctness of such oxygenised water, and of a similar oxygenised carbon dioxide described by Schützenberger, is however to be desired before the existence of such dissociation can be established.

12. We have now considered two kinds of chemical union:—(1) heterogeneous integration, or the identification of volumes of unlike species, and (2) homogeneous integration, or the identification of volumes of like species, in which consists the so-called polymerisation and most cases of allotropism. Both of these modes of union have a wide range, dependent on pressure; and the gaseous species formed by the first process become, like the elements themselves, the subjects of the second process. The process of integration by successive steps gives rise to homologous or progressive series, as in the paraffines, the olefines, the acetylenes, the benzenes, and other hydrocarbonaceous series, in recognised species of some of which the coefficient of the carbon is not less than 30. In the olefines, $n(CH_2)$, the first term being the same as the common difference, all the succeeding members of the homologous series are polymers thereof, constituting what we have called *isomeric homologues*. This name serves to distinguish them alike from those homologous series in which the first term is unlike the common difference, and which are *anisomeric homologues*, and from these isomeric compounds which are formed by successive homogeneous integrations, and between which, as between the allotropic forms of the elements, there is no apparent homology or similarity of function.

Familiar examples of such allotropic derivatives of species, themselves formed by heterogeneous integration, are seen in the successive condensations or homogeneous integrations of pentine, of acetylene, of cinnamene, and of the aldehydes, some of which take place spontaneously or with very slight provocation not only in gaseous but in liquid species. Besides the olefines among the hydrocarbons, we find in bodies like the carbon-spars $n(CMO_3)$, examples of what must be regarded as isomeric homologues, and perhaps, though less apparently so, in the different allotropic forms of the titanium and silicon dioxides, wherein that similarity of function which marks homology is either non-apparent, from their chemical indifference, or else is absent. The latter is evidently the case in many cases of compounds the empirical formulæ of which present good examples of progressive series, as in the metallic oxides, sulphides, and arsenides. An illustration of this is afforded in the observed compounds

of manganese with oxygen, among which are MnO , Mn_2O_4 , Mn_2O_3 , Mn_2O_8 , MnO_2 , MnO_3 , Mn_2O_7 , and MnO_4 , which, however, with but two exceptions, are known to us not in gaseous species, but only in highly condensed forms.

13. As the higher hydrocarbons of the various progressive series are built up by the integration of successive units of CH_2 with the first term of each series, so the monovalent alcohols and the corresponding ammonias are generated in a similar manner from H_2O and NH_3 . The capacity of such integration, or, in other words, the fixing power of such an integer as H_2 , HCl , or NH_3 , is very great, and theoretically knows no limit. By this consideration our conception of so-called atomicity or valency, which for an element has been defined as "its atom-fixing power measured by atoms of hydrogen" (J. P. Cooke), is greatly enlarged. Thus measured, chlorine is made monovalent, carbon tetravalent, and sulphur, like oxygen, divalent, although from its union with O_3 its hexavalence has been affirmed, a view which is sustained by the hexiodide of sulphur of Landolt, Si_6 , and by the crystallised artificial sulphide of iron and nickel of Mackintosh (SFe_4Ni_2), while from the described iron sulphide, SFe_8 , its octovalency would follow. Indeed, as there is reason to believe that the compounds of metallic iron formed in the blast-furnace with much smaller proportions of sulphur are homogeneous, it may be maintained that there is no limit to the valency of sulphur save that determined by the integral weight of the element on the one hand and that of the very highly condensed species known to us as molten iron on the other. Similar conclusions follow from the solution of carbon in the same metal, forming therewith compounds in which the hardness, fusibility, and magnetic relations of the metal are modified in a notable manner. The characteristic properties of the apparently homogeneous compounds of small proportions of both silicon and phosphorus, alike with iron, with copper, and with other metals, and those of various metallic alloys, will at once suggest themselves to the chemist. In this connection may also be mentioned for illustration the solution of oxygen in molten copper, and that of the same gas in melted silver, forming a compound stable at high temperatures, but disintegrated on cooling at the ordinary pressure.

14. The power of fixing hydrogen possessed by various metals is not less instructive. The amount retained by palladium corresponds to Pd_2H , while potassium and sodium form therewith compounds of a certain stability, represented respectively by K_2H and Na_2H .* The capacity of the latter compounds to unite with smaller additional quantities of hydrogen, and that of other metals to combine with small amounts of the same elements, show that the limit to be assigned to this power of fixing hydrogen by various metals presents as wide a range as that observed by the metals for sulphur, phosphorus, silicon, or carbon. The fixation of bodies in chemical union or solution is not the prerogative of one element rather than another, as the popular statement of the doctrine of valency would seem to imply. The question of the stability of a chemical compound, whether formed by homogeneous or by heterogeneous integration, is one of temperature and pressure; and heat, which readily effects the disintegration of the hydrides just mentioned, decomposes either wholly or partially, at the atmospheric pressure, many metallic oxides. That the amount of one body retained in union with another is thus dependent on temperature, the pressure being constant, is well illustrated by the experiments of Spring on the arsenides of cadmium. The native metallic arsenides have for 100As quantivalent ratios for the metals represented by 33.3, 60, 66.6, 100, 150, 300, and 500, the latter $=1:5$ being generally regarded as representing the maximum fixing power or atomicity of arsenic, hence designated as penta-valent. When, however, cadmium is fused with an excess

* Troost and Hautefeuille, *Comptes Rendus*, lxxviii., 968.

of arsenic at a low red heat, a large part of this is volatilised, and there remains a very hard metallic body giving essentially the ratio 1 : 6. It was not found possible to get by way of fusion a compound retaining a larger amount of arsenic, and this for the evident reason assigned by Spring, that "at the elevated temperature at which the combination of cadmium and arsenic takes place under ordinary pressure, the tension of dissociation is such that an arsenide is produced containing but little arsenic."* At ordinary temperatures, on the contrary, or under strong pressure, we have not to reckon with this tension of dissociation, and we readily get combinations containing a larger proportion of the volatile element. It is not the metal-fixing power of the arsenic, the oxygen, the sulphur, or the hydrogen, but rather the power of the metal to fix these more volatile elements under various conditions of temperature and pressure which we have to consider.

15. The ideal gas responds perfectly to external pressure, obeying implicitly Boyle's law; the ideal solid is, on the other hand, theoretically incompressible. Gas and solid are, however, alike expansible by heat, and this dynamic change of volume by thermic expansion, which is regular and constant, is thereby distinguished from changes of volume from chemical metamorphosis, which are periodic. Thus, at the standard pressure, water below 0° is a solid, while from 0° to 100° it is liquid, and above this point a vapour, which, so far as observed, has, like the liquid, its own nearly constant rate of thermic expansion. The vapour of sulphur, however, which from 450° to 550° has a density ninety-six times that of hydrogen, assumes above 800° a density only thirty-two times that of hydrogen. In the case of iodine-vapour, and of the vapours of fluorhydric acid, of nitric peroxide, of acetic acid, of acetic aldehyd, of many hydrocarbons, and of solids which like arsenic, phosphorus, and tin undergo allotropic transformations, we see examples of the same periodic chemical changes.

16. The question of greater or less density of gas or vapour for elements, and for so-called polymeric species, as compared with that of the hydrogen unit, is a question of greater or less homogeneous integration. Moreover, the gaseous, liquid, or solid condition is theoretically wholly dependent on temperature and pressure, as pointed out in § 6. It is known that liquid species, if not subject to heterogeneous disintegration by heat, pass thereby, under increased pressure, into vaporous forms far denser than the normal vapours, which, while having the character of condensed or polymeric species, are stable only within certain narrow limits, and alike by increase of temperature and by diminution of pressure are changed, through homogeneous disintegration, into less condensed vaporous species. The genesis and the transformations of these heavy vapours thus imply a chemical process analogous to that observed in the denser and lighter vapours of sulphur, iodine, fluorhydric acid, nitric peroxide, acetic aldehyd, and acetic acid.

W. Allen Miller long since pointed out that the dense vapours of ether and alcohol formed just above the critical points of these liquid species have tensions far less than belong to the normal vapours, and, moreover, that the abnormally dense vapours of these liquids on augmentation of temperature not only present a much greater rate of expansion than air or water vapour, but, instead of being like these, constant therein, show a rapidly increasing coefficient of dilatation.† These phenomena, as we have elsewhere remarked,‡ are in accord with those presented by sulphur, which, near its point of condensation, yields a dense hexad vapour readily disintegrated at a higher temperature (and doubtless also by reduced pressure) into a less dense diad vapour. Applying, then, Boyle's law to the tension of ether vapour as observed just above its critical point, we find it to be not the normal vapour, but

a highly condensed polymer, which, by increase of temperature, is metamorphosed into less and less condensed species, as shown by the very rapid increase of the elastic force as compared with that of air under similar conditions of temperature and pressure.

In illustration of this point we may note that Ramsay and Young have lately observed that the vapour of alcohol at 243° has a tension of only 63 atmospheres and a specific gravity of not less than 0.280, water being 1.000. This corresponds to a fourfold condensation, $4(C_2H_6O)$, since the normal vapour of alcohol calculated for that temperature and pressure should, according to Boyle's law, have a specific gravity of 0.0684, or but one-fourth of the number observed.

(To be continued.)

CORRESPONDENCE.

ANALYSIS OF FERTILISERS.

To the Editor of the Chemical News.

SIR,—Mr. Buchan (CHEMICAL NEWS, vol. lviii., p. 195) raises the question of a possible source of error existing in the results of my experiments on the determination of P_2O_5 (CHEMICAL NEWS, vol. lviii., p. 170); I therefore desire to state that when conducting these experiments, with a view to ascertaining the effect produced on the determination of the P_2O_5 when it is omitted to bring the acid solution of phosphate to complete dryness, prior to its precipitation, I did not overlook the possible formation of pyrophosphate below a temperature of 150° , but took care to avoid, and otherwise prove, the absence of such source of error before asking you to publish them.

Mr. Buchan suggests that my letter leads to the conclusion that, in the majority of cases, the determinations of P_2O_5 by the magnesia method are too high, also that it presses very sorely and unfairly against manure manufacturers: to this I have to say, as regards the former conclusion, that if, in the majority of cases, the evaporation of the acid solution of the phosphate to complete dryness be neglected, then in the majority of cases the results obtained are too high; such is my experience. As to the latter conclusion, my letter was not written with any intention of doing injustice to manufacturers, though I take no cognizance of trade interests in the matter, for it is purely a question of principle, of chemical accuracy; and I think Mr. Buchan will be disposed to admit that if the whole of the silica be rendered insoluble in analysing the raw materials purchased, and the same mode of procedure applied in the analyses of the manufactured goods vended, neither his firm nor the purchasers of their fertilisers will suffer any injustice.—I am, &c.,

ALFRED FIRBY.

98, Albion Street, Leeds,
October 23, 1888.

ARSENIC IN THE HOME.

To the Editor of the Chemical News.

SIR,—The article by Mr. A. W. Stokes under the above heading, which appeared in the CHEMICAL NEWS (vol. lviii., p. 189), is very interesting, in so far that it shows that the use of poisonous pigments is being again revived in a perfectly needless way.

In 1860 or 1861 Prof. A. W. Hofmann drew attention to the fact that arsenical pigments were largely used in colouring the green fabrics, at that time used very extensively for ball dresses. So serious was the scare produced that I frequently had to examine twenty-five materials per week for arsenic. Schweinfurth green was the pigment usually met with. Green wall-papers had fallen into bad repute, in sympathy with these green-coloured fabrics.

* Formation de quelques arsénures métalliques par l'action de la pression. 1883. *Proc. Roy. Acad. Belgique*, (3), v. No. 2.

† Miller, "Chemical Physics," 3rd edition (1863).

‡ "A New Basis for Chemistry," 2nd edition, § 117.

Now when we consider how these pigments were applied to the "tarletans" used for ball dresses, we can hardly be surprised at the result likely to follow. Ultimately these pigments gave way to a green dye, produced by superposing a yellow on an indigo-dyed fabric.

In testing these fabrics with Marsh's apparatus a serious trouble was met with in the frothing which invariably took place. Reinsch's test was on this account prepared, ordinary fine copper wire, as used for electrical purposes, being used.

Many people who sit for any length of time in a room papered with a green coloured paper complain of headache. Some years ago a friend of mine gave me some dust swept off a bookcase which belonged to his studio, which was covered with a green flock paper. There was no difficulty in finding arsenic in the dust, which was ultimately referred to the paper.

Some green pigments which are not arsenical are impregnated with arsenic, from its being an accidental impurity, and here, I am afraid, would be found some difficulty in the way of legislation.

I met with a sample of copper wire which had an electrical conductivity of only 30 per cent that of pure copper wire. Arsenic was suspected of being present; the wire was found to contain about 5 per cent metallic arsenic. We have only to imagine Brunswick green being derived from the same source as this wire to realise the difficulty. Zinc and antimony often contain more than copper.

What is to be the fate of fireworks containing arsenic or mercury? Many enamels are rich in arsenic.

The use of poisonous materials cannot be too highly censured, however, employed for such purposes as mentioned by Mr. Stokes. Publicity is the safest check against the unnecessary employment of dangerous chemicals or processes. A tradesman or manufacturer pays more regard to an outburst of popular indignation than he does to an Act of Parliament.—I am, &c.,

THOMAS T. P. BRUCE WARREN.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 14, October 1, 1888.

This issue contains no chemical memoirs.

Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 4.

A Spirit Furnace.—Paul Schoop.—A memoir of little interest.

A Gas Burner.—F. P. Venable.

A New Form of Liebig's Condenser.—E. Hart.

On Burettes and Pipettes.—W. O. Attwater and C. B. Woods.

A Burette for Titration with Solution of Permanganate.—Clemens Jones.—These four papers are from the *Journal of Analytical Chemistry*.

Bottle for Filling Burettes.—A. Stein (*Chemiker Zeitung*).—This device is shown in a figure, but does not admit of intelligible description.

An Absorption Apparatus for Burettes with Overflow Points.—A. Beutell (*Chemiker Zeitung*).—An arrangement to prevent the absorption of carbonic acid in the use of caustic alkalies, and especially baryta-water.

A Bottle Burette.—F. H. Morgan.—From the *Journal of Analytical Chemistry*.

Drying Apparatus.—K. Ulsch.—This apparatus consists of a glass tube provided below with a narrow aperture for receiving the material to be dried, which must not occupy more than half the space. This glass tube is fixed in a copper tube, somewhat wider, closed below and provided above with a lateral tube, so that the air-space thus formed is tightly closed above. The glass tube is placed in connection with an aspirator, whilst the side-piece of the copper tube allows dried air to enter. R. Rempel describes (*Chemiker Zeitung*) a similar apparatus, consisting of two concentric cylinders.

Air-bath with a Constant Temperature in Different Parts of the Internal Drying Chamber.—Hermann Rohrbach (*Chemiker Zeitung*).—This apparatus cannot be intelligibly described without a figure.

Vacuum Drying Apparatus.—P. Schoop (*Zeitschrift für Chemische Industrie*).—The same remark applies to this paper.

Water-Sprengels.—O. N. Witt (*Chemiker Zeitung*).—This apparatus is constructed on the principle already proposed by Mendeleeff, Kirpitscheff and Schmidt, Jagno, and Linnemann. It is represented in the two accompanying figures.

A Water-Sprengel.—R. Law.—From the *CHEMICAL NEWS*.

The Action of Water-Sprengels.—E. Pfleger (*Chemiker Zeitung*).—The author mentions that when the pressure in the recipient is reduced to a minimum the air is almost absolutely removed, and the slight remaining pressure is due to watery vapour. If monohydrated sulphuric acid is allowed to enter the recipient after it has been cut off from the pump, the watery vapour is absorbed. In consequence a further reduction of temperature takes place, so that an almost perfect vacuum is obtained. But if the acid is introduced beforehand into the recipient it causes, after a certain point of exhaustion is reached, a current of watery vapour to flow into the recipient, and prevents the remaining air from escaping. The vacuum obtained in this manner is less perfect than one produced without the use of sulphuric acid.

A Circular Mercurial Pump.—K. Antolik.—The apparatus is not described.

Arrangements for Rapid Filtration.—Clemens Jones.—From the *Journal of Analytical Chemistry*.

The Filtration of Tedious Liquids.—A. B. Clemence.—From the *Journal of Analytical Chemistry*.

A Modification of Soxhlet's Extraction-apparatus.—J. J. Barlow.—From the *CHEMICAL NEWS*.

Apparatus from Fractionated Distillation.—U. Gayon.

Two Arrangements for Collecting Gas out of Liquids contained in Corked Bottles.—C. Reinhardt.—These two memoirs are not adapted for useful reproduction.

Apparatus for Generating Pure Oxygen in Quantity.—Br. Tacke.—The author describes in *Chemiker Zeitung* an improved form of his original apparatus. Instead of the iron tube he uses one of brass, the bottom of which is joined on with hard solder.

The Production of Sulphurous Acid in Quantity.—H. N. Warren.—From the *CHEMICAL NEWS*.

An Excellent Reduction Agent for Analysis in the Dry Way.—F. Nelissen.—The author recommends sodium formiate, which he prepares by neutralising crude formic acid (as obtained in the well-known manner by distilling glycerin and oxalic acid) with soda-lye free from sodium sulphate, evaporating the solution to dryness, and desiccating at 130°. The action of sodium formiate depends on the circumstance that at elevated temperatures it is resolved into sodium carbonate with liberation

of hydrogen and carbon monoxide. The reductive action of these gases in the nascent state is so powerful that lead, copper, bismuth, antimony, and silver are obtained at once in metallic globules, even in the oxidation flame.

Separation of Nickel and Cobalt from Iron.—J. B. Mackintosh.—The author revives the old method, depending on the different behaviour of the sulphides with dilute hydrochloric acid. He throws down the metals from a boiling solution with ammonium sulphide, and treats with dilute hydrochloric acid. In this manner is obtained a residue containing nearly all the nickel and cobalt with mere traces of iron and a solution containing almost all the iron, with but small quantities of nickel and cobalt. The iron is separated in the well-known manner as a basic salt both from the residue and the solution, an operation which is easier and more expeditious than the separation of the three metals by direct basic precipitation.

The Action of Sulphuretted Hydrogen upon Arsenic Acid.—B. Brauner and F. Tomicek.—The authors confirm the statement of R. Bunsen that on precipitating an acid solution of an arseniate according to his directions arsen-pentasulphide is obtained.

A Reaction for Aldehyds.—Michael and Ryder.—From the *American Chemical Journal*.

Detection of Aldehyd.—W. Windisch (*Chemiker Zeitung*).—The author uses metaphenylene-diamine hydrochlorate. If a freshly prepared aqueous solution of this salt is added to an aqueous or alcoholic solution of aldehyd there appears a yellow zone, which disappears on the addition of the fixed alkalies or ammonia, and is restored on the addition of hydrochloric acid.

The Detection of Acetic Acid in Presence of Morphine.—G. Stillingfleet Johnson.—From the *CHEMICAL NEWS*.

Determination of Nitrogen in Organic Matters.—"The Association of Official Agricultural Chemists."—From the *CHEMICAL NEWS*.

Determination of Alkaloids with Meyer's Reagent (Potassium Mercury Iodide).—A. B. Lyons.—From the *American Journal of Pharmacy*.

Methods for Determining the Amides in Vegetable Extracts.—E. Schulze.

Determination of the Nitrogen of Ammonia of the Amide-amidic and Amine-amidic Compounds in Natural Products.—Antonio Longi.—These memoirs are merely mentioned without being abstracted.

Determination of Glycerin.—L. Legler.—The author proposes to oxidise crude glycerin with potassium dichromate and sulphuric acid, and to deduce the quantity of glycerin from that of the carbon dioxide formed. Methods have also been proposed by Messrs. Cross and Bevan (*CHEMICAL NEWS*), O. Hehner (*Analyst*), E. Baumann, R. Diez, A. H. Allen (*Analyst*), and Jolles.

The Volatility of Glycerin along with Watery Vapour.—Otto Hehner.—From the *Analyst*.

The Examination of Fats.—This memoir will be inserted at length at the earliest opportunity.

The Use of Congo Red as Indicator in Ascertaining the Reaction of Urine.—E. Brücke.—Ammoniacal salts decidedly interfere with the examination by means of congo-red. Acid salts, such as acid ammonium or potassium tartrate, affect congo-red in the same manner as urine.

Determination of Nitrogen in Urine.—W. Camerer.—Not adapted for abstraction.

A Modification of the Soda Test for Carbon Monoxide Hæmoglobine.—E. Salkowski.—The blood is mixed with twenty parts of distilled water, and a portion is mixed in a test-glass with an equal volume of 1.34 sp. gr. Carbon monoxide blood becomes dullish white, then a bright light red, and on standing separates into light-

red flakes which collect on the surface, and a faint rose-coloured liquid. Normal blood, if similarly treated, turns a dirty brown colour.

Detection of Sulphuretted Hydrogen in Urine.—F. Boneko.—The author uses the methylene blue reaction. The sample is mixed with five drops of hydrochloric acid, one to two drops solution of ferric chloride, and a few grains of paramido-dimethylaniline hydrochlorate.

Approximate Quantitative Determination of Peptone.—E. Salkowski.—The author employs the xanthoprotein reaction.

Ferments in Normal Urine.—Like Leo and H. Hoffmann, E. Stadelmann was able to detect a peptic but not a tryptic ferment in normal urine.

The Examination of Gastric Juice.—This memoir does not admit of useful abstraction.

The Toxicological Detection of Bromine and Iodine.—Vitali.—If 1 grm. bromine or iodine is dissolved or suspended in water and brought in contact with at least 300 grms. finely minced flesh, every smell of the halogens disappears in a few minutes, and no trace of them is to be found in a free condition, as they are principally converted into halogen hydracids, which exist partly in the free state and partly in combination with albumenoids. These compounds are soluble partly in alcohol but partly only in water. The halogens can be obtained from the residue of the extracts by treatment with caustic alkali.

Chemico-legal Detection of Blood-stains.—Ferry de la Bellone (*Chemiker Zeitung*).—Tissues upon which blood is suspected are reduced to fibres and let float on the surface of a dilute solution of sodium chloride (1:1000). If blood is present the liquid takes a brownish rose colour, which may be more closely examined by means of the spectroscope. If hæmoglobine is recognised a drop or two drops of solution of chloral are added to the contents of the test-tube. There is formed a rose-coloured precipitate, from which, after settling, the supernatant liquid is removed with a pipette. A drop of the residual matter is laid upon a glass slip, which is then moved up and down over a small alcohol flame. The pale liquid is removed from the reddish coagulum by means of slips of filter-paper. The clot is then stained with magenta, the excess of colour removed with water, a drop of acetic acid is added, and the glass cover is put on. Under the microscope the dyed globules are recognised by their characteristic form. If the suspicious spot is found upon instruments, wood, or paper, they are scraped, and the scrapings are suspended in a little bag in the sodium chloride. If soil is soaked with blood the particles which are thus coated are selected out under a low magnifying power and treated as above.

Re-determination of the Atomic Weight of Thorium.—Gerhard Krüss and L. F. Nilson.—The vapour-density of thorium chloride confirmed the quadrivalency of thorium.

Revue Universelle des Mines et de la Metallurgie.
Vol. ii., No. 3, June, 1888.

Determination of Sulphur in Commercial Irons and in Sulphides Decomposable by Acids.—Dr. L. L. de Koninck.—In 1870 the author published a process for the determination of the sulphuretted hydrogen given off by sulphuretted iron on treating them with hydrochloric acid or dilute sulphuric acid. This process consists in condensing the sulphuretted hydrogen in a series of three small washing-bottles containing a neutral solution of silver nitrate at two per cent; in collecting the precipitate of silver sulphide and determining the sulphur. This determination is effected by treating the precipitate with bromine in presence of water, filtering off the silver bromide, and precipitating the sulphuric acid formed with barium chloride. The barium sulphate formed is very pure, being produced in a liquid free from fixed matters.

Latterly the author has sought to simplify the process by substituting mercury for silver; the mercury forming, with bromine in excess, a soluble and volatile product, the advantages of the original process would be retained, and the filtration and washing of the precipitate of silver bromide would be avoided. To this end he absorbs the sulphuretted hydrogen in a mixed solution of mercury cyanide and ammonium chloride. This mixture readily absorbs the sulphuretted hydrogen, giving a black flocculent precipitate which is easily collected on a filter and washed. On treatment with bromine and water it dissolves rapidly and completely, especially at a slightly elevated temperature, yielding sulphuric acid and mercury bromide. This process has been carefully verified and found strictly accurate.

Determination of Manganese in Steels.—Franck Julian.—One grm. of metal is dissolved in 15 c.c. of nitric acid (sp. gr. 1.2), evaporated down to 5 c.c., 20 c.c. of strong acid are added, and the liquid is precipitated in heat by potassium chlorate, avoiding a large excess. There are then added successively to the mixture 5 c.c. of strong nitric acid, 60 c.c. hot water, and 10 c.c. of the oxalic solution. The liquid is agitated until it takes a light yellow colour, and the excess of oxalic acid is titrated by means of permanganate, operating at a temperature of about 70°. The manganese dioxide dissolves rapidly under the influence of oxalic acid; the back titration is done quickly, and the end of the reaction is easily found after a little experience. The solutions employed are:—Ammonium oxalate at 15 grms. per litre. Potassium permanganate at 1.6 per litre. To determine the standard of the permanganate we take 10 c.c. of the solution of oxalate, add 50 c.c. of hot water, and the nitric solution of 1 grm. of steel, from which the manganese has been eliminated by precipitation with potassium chlorate and separating the precipitate with an asbestos filter.

Vol. iii., No. 1, July, 1888.

The only chemical matter in this number is a translation of the Presidential Address delivered by Mr. Crookes before the Chemical Section of the British Association at the Birmingham Meeting, 1886.

No. 2, August, 1888.

Arrangement for Titration in Heat.—Prof. L. L. de Koninck.—The apparatus devised for this purpose cannot be described intelligibly without the accompanying figure.

NOTES AND QUERIES.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment, with Attachment for Filtration with Exclusion of Air; in Wood, Iron, or Bronze every desired size

Experimental Filter Presses

in Wood, Iron or Bronze.

Filtration Experiments, if desired, carefully conducted in our Laboratory).

Steam Pumps & Transmission Pumps, horizontal, vertical, mounted on column, Wall Pumps, Pumps for Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids. "Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids, any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof, i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c. Also Small Ice Machines for Families, Laboratories, Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure, or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Compound Steam Engines. From 2—150 horse-power

Steam Water Pumps,

newest, most approved Construction, taking up little room, and especially suitable for placing in Wells, with great efficiency; up to largest sizes.

Compressors driven by Steam or Belt, for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon, Ether, Alcohol, Acetone, Water; In Iron or Copper. (Extraction Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.

Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans, and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin Refineries, Resin Distilleries, Paraffin Works, Tar Distilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest References for our above-named Specialities on Application.

EMPTY PETROLEUM BARRELS.

Empties may be delivered for our account to—

ATLANTIC WHARF, BOW COMMON,
WESTERN WHARF, OLD KENT ROAD,
Or THAMES HAVEN PETROLEUM WHARF, THAMES HAVEN.

WE ALSO RECEIVE EMPTIES AT THE VARIOUS LONDON RAILWAY DEPOTS

The same Price paid for Barrels branded with our own Brand, "LUSTRE," as for Barrels branded with American Brands.

NOTICE.—In the case of Empties sent for our account to Thames Haven Wharf or a Railway Depot, please advise us when sending, and mark K on the end of the barrels in Red Paint, that we may recognise them.

DEDUCTIONS FOR DAMAGE.—Broken Chime or Stave 6d. Broken Head 6d. to 1s. 6d. according to extent of damage.

COMPANY'S STEAMERS:—

"ELBRUZ," 3700 Tons of Oil capacity.
"KASBEK," 3700 " " "
"ARARAT," 3700 " " "

SPECIAL NOTICE.—As our Oil would be seriously damaged if put into Barrels that have contained Paraffin Oil, Paraffin Empties are useless to us, and we are compelled therefore to decline to receive them.

THE KEROSENE COMPANY, LIMITED,
26, GREAT ST. HELENS, LONDON, E.C.
IMPORTERS OF RUSSIAN PETROLEUM.

PETROLEUM JELLY,

EQUAL TO AND CHEAPER THAN VASELINE.

SANITARY FLUID AND SHEEP DIP,
THE CHEAPEST AND BEST DISINFECTANT.

GREASE, PITCH, ASPHALTE, AND ALL PRODUCTS OF TAR AND RESIN.

Samples and Prices on application.

GRINDLEY AND CO. POPLAR LONDON E.

**Short-Beamed
Analytical
Balances.**

OTTO WOLTERS.

Estab.
1875.

Manufacturers of Mica Goods for Philosophical and ALL purposes.
Contractors to Her Majesty's Government.

THE CHEMICAL NEWS.

·VOL. LVIII. No. 1510.

THE AUSTRALASIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

BEFORE proceeding to the agreeable task of noticing the admirable Inaugural Address of the President, Mr. C. H. Russell, we must bestow a glance at the constitution of the Association. This body, though founded upon the lines of the parent Association in the Home Kingdoms, differs from it in several respects. It has retained that objectionable feature, the Section for "Economic Science and Statistics." We say objectionable, because statistics must be regarded, not as an independent science, but as a method, applicable in various science. As for "Economic Science," experience has proved that the deliberations of such a Section border too closely upon politics to be either safe or desirable. We cannot help, also, looking with a certain jealousy upon the creation of a Section for "Literature." It has been too often found, in the so-called "Literary and Philosophical Societies" of Britain that literature monopolises too much of the attention and resources of the Society, and regards science with something more than mere passive dislike.

Mr. Russell, in his impressive and brilliant address, after noticing the part played by the British Association, especially in its earlier days, argued with great justice that in so vast and thinly-peopled a continent as Australia an analogous body to bring to a focus the scientific ability and the research scattered throughout the colonies was even more needful. He was then compelled to combat the old enemy, utilitarianism. He quoted a "well-known politician in another colony who, when asked to spend a few pounds on pure science, replied:—'Will it affect the price of beef and mutton? If not I won't spend a shilling on it.' This old delusion, which still haunts the British Empire though our most formidable rivals have got rid of it, was ably exposed by Mr. Russell.

The President did not feel himself compelled to a direct encounter with the Ethical School of Utilitarians, who, on hearing of researches, astronomical, chemical, or biological, sneeringly ask if we could not be "good and happy" if nebulae and rare earths and microbia had never existed? But he could not help referring, though briefly and very courteously, to the jealousy with which the progress of Science is regarded by the students of the so-called "humanities." He said:—"There have been those who said that the proper study of mankind is man, and who, while strenuously denying to this study the dignity of a science, have thought no other science worthy of culture. And there have been others who have asserted that man's only study was nature in the things around him, neglecting altogether the science of man." To these two views Mr. Russell replies:—"But man and nature are correlative, and therefore true; science must embrace both studies." This, we submit, is scarcely a satisfactory answer. Man is part and parcel of nature, though its most complex and highly differentiated part, and in that light alone can he be successfully studied.

The jealousy of the progress of science felt by the literary world found its expression from the mouth of no less important a person than Sir William Manning, Chancellor of the University of Sydney. This gentleman contrasted Science with a something which he called "general education." He expressed a hope "on behalf of the University that the attractions of Science will not take the youth of this colony too much away from general education. There is no doubt Science has great attractions which may lead many not to study the writings of

antiquity." This view, which was again and again put forward during Sir W. Manning's speech, is profoundly to be regretted if we are to take it as the voice of the University of Sydney.

Some of the New South Wales papers comment upon what they call the "unevenness" of the programme of the Association. The sections in which the number of papers to be read is large were those of chemistry and mineralogy, geology and palæontology, biology, anthropology, and architecture and engineering. The section devoted to astronomy, mathematics, physics, and mechanics is moderately well occupied, but in the sections for geography, economics and statistics, sanitary science, and literature and the fine arts the entries number only three each.

Now this "unevenness" is precisely what must follow if Australian men of science obey the good old rule of doing the work that lies close at hand. In chemistry, geology, and biology, with their allied branches, there are evidently a vast number of questions which can be successfully taken in hand only in Australia. On the other hand, a residence in the Colonies offers no special facilities for the study of mathematical, physical, mechanical, economic, or literary subjects, and these latter, therefore, were wisely left in comparative abeyance.

The newspapers, however, have unfortunately taken a different view of the matter, and have reported the economic papers at great length, whilst the proceedings in the chemical and geological sections have received but scanty notice.

THE VALUATION OF OIL-CAKE.

By THOMAS T. P. BRUCE WARREN.

COTTON-CAKE is preferred to linseed-cake as cattle food, but it is easy to understand that several kinds of cake may be mixed together. A short time ago Mr. Voelcker pointed out, in the *CHEMICAL NEWS*, the use of the microscope for detecting this.

In the *CHEMICAL NEWS* (vol. lviii., p. 196) is an extract on "Determination of Fatty Matter in Linseed-Cake." The author points out that in drying the cake there is a diminished yield of oil.

Now this is quite easy to understand; the residual oil contained in a cake is very liable to oxidation, and a thoroughly oxidised oil is practically insoluble in any solvent. Crushed poppy-seed is remarkable in this respect; and, as a rule, the insolubility of the residual oil is just in proportion to its tendency to oxidise: heat invariably facilitates this. In drying an oil-cake the same precaution should be taken as in drying an oil or fat, but which unfortunately seems neglected.

It is better to remove the oil by solvents first, especially if a well-defined drying oil is present, and to allow the water to subside in a warm place, in a well-closed vessel, so as to avoid oxidation. By passing a current of ozonised oxygen into the oil it is quite easy to form some idea of what we are dealing with; by noting the difference in the iodine absorption, an oil easily oxidised—as poppy, linseed, and hempseed—is detected from rape and cotton. If the extracted oils are "blown," with heat applied at the same time, the two latter oils can be detected by the colour of the coagulum produced by sulphur chloride. Cotton oil yields a much lighter product than the other oils: the dark colour results principally from the liberation or expulsion of glycerin; the free fatty acids yield dark, and in some cases black, products.

It is not an uncommon thing to find oil-cakes containing rosin oil, the inference being that the marc is nearly exhausted, and then the oily matter made up with oils from other sources.

The same oils oxidised cannot be considered equal as heat producers.

The electrical resistance of an oil extracted from a

pure cotton-cake is enormously higher than the oil yielded by any other oil-cake; then follow, in order, rape, poppy, and linseed.

When the powdered seeds are steamed previous to crushing it ought not to be forgotten that we are bringing about a condition favourable to oxidation, but the same thing will happen by simple exposure. The crushed linseed sold by druggists for medical purposes rapidly changes, by the oxidation of the oil, if exposed in an open vessel.

THE FOUNDATIONS OF CHEMISTRY.*

By T. STERRY HUNT, LL.D., F.R.S.

(Concluded from p. 206).

17. THE progressive stages which in sulphur, iodine, fluorhydric acid, and acetic acid are marked in the process of homogeneous disintegration by heat at the ordinary pressure, do not, however, occur in the cases of ether, alcohol, water, and similar volatile liquids, except when these are heated under increased pressure; conditions under which all liquids not thereby exposed to heterogeneous disintegration may theoretically assume the gaseous state. The intermediate forms in the metamorphosis of volatile species are of very different degrees of stability, and while in many cases capable of existing at the ordinary pressure through a certain range of temperature, in others exist only within such narrow limits of temperature and pressure that we are led to conjecture from analogy that within still narrower limits there may exist many other intermediate species hitherto unknown and unsuspected. It may even be supposed that every variation in pressure acting upon compressible species gives rise to some passing chemical change too fugitive to be detected. It is known that variations in pressure control the production of allotropic forms in the case of solids, and may we not from analogy expect the same principle to apply in the action of pressure upon all bodies which depart from the theoretical elasticity of the perfect gas? The ideal gas responds perfectly to every variation of pressure, according to Boyle's law, while the ideal solid is on the contrary incompressible (§ 15), but the representatives of both of these can exist only within certain limits of temperature and pressure.

18. The seeming continuity of the liquid and the gaseous states of matter, as seen in the dense vapours discovered by Cagnaird de Latour, and the fact that gaseous matter by successive condensations under great pressure assumes at high temperatures a condition not of liquidity, but of dense gas or vapour, as set forth by Andrews, receives a remarkable illustration in the discoveries of Hannay and Hogarth.† These chemists have found not only that solutions of salts in alcohol and ether have their critical points, above which they pass integrally into the state of dense vapours, but that the dense vapours of the solvent liquids themselves have, like condensed hydrogen gas, the power to take into solution various solids. The fact that water (and probably watery solutions also) will pass into the state of dense vapour not far from 400° (as long since shown by Cagnaird de Latour), and that this vapour is, moreover, as found by the authors just cited, a solvent alike for silica, alumina, and zinc oxide, is one which throws great light on many problems in geogony and physiological mineralogy. It leads us to conclude that liquid water does not exist in highly heated rocks at considerable depths from the earth's surface, where, however, it may be present either in chemical combination, reducing their fusing point, as shown in the late researches of Tilden and Shenstone, or liberated, and pervading them as

a dense vapour, holding dissolved mineral elements to be subsequently deposited as crystalline species. The above facts serve to show that a solution is really an integral chemical compound, in accordance with the view long maintained by the author.*

19. The law of volumes prevails in all known cases both of homogeneous and heterogeneous integration among gases and vapours, in the changes of oxygen, and of the vapours of iodine and sulphur, as in those of fluorhydric acid, of aldehyd, and of pentine and its polymers, as well as in the not less remarkable condensations or polymerisations of acetylene. All analogy leads us to extend this law to the still greater condensations observed in the denser vapours into which liquid species, above their critical points, are resolvable, and to the further condensation of the vapours into liquid and solid forms—to assume, in fact, that the law of combination by volume, like that of combination of weight (with which, so far as experiment goes, it is indissolubly linked), is universal.

The coefficient of condensation in the case of gases and vapours is readily found by comparing the densities of the respective species at standard temperature and pressure, in the way well known to chemists; the weight of a given volume of hydrogen gas at that temperature and pressure being the unit. For the liquid and solid species formed by the homogeneous integration of these gases and vapours, as we have elsewhere endeavoured to show, the weight of the same volume of the newly formed species at the temperature of its production under the standard pressure is to be taken as the term of comparison, either with that of the vapour or gas calculated for 0° and 760 m.m., or finally, with the weight of an equal volume of hydrogen gas at the same temperature and pressure.

As declared by the writer in 1853, "the doctrine of chemical equivalents is that of the equivalency of volumes"; in other words, the law of volumes, like the law of weights, is universal, and for all species—liquid, solid, or gaseous—the volume, under proper conditions of temperature and pressure, is the same. The volume being then a constant quantity, the integral (or so-called equivalent or molecular) weight of any species, whether gaseous, liquid, or solid, is its specific gravity, hydrogen gas being unity.

20. The advantages to be gained by establishing a single unit for specific gravity, and by substituting alike for water at its maximum density (in the case of liquids and solids) and for air at 0° and 760 m.m. (in the case of gases and vapours), hydrogen gas at the same temperature and pressure (a plan first indicated in the writer's volume entitled "A New Basis for Chemistry"), were urged in a paper entitled "Chemical Integration," read before the National Academy of Sciences in April, 1887, and published in the *American Journal of Science* for the following August. They were further insisted upon in a paper on "Integral Weights in Chemistry," read before the British Association for the Advancement of Science, at Manchester, in September, 1887, and published in the *London, Edinburgh, and Dublin Philosophical Magazine* for October of the same year. The integral weights of all gases and vapours are evidently their specific gravities, hydrogen being unity; and since water itself is the unit of specific gravity, adopted for convenience, for all liquids and solids, it becomes of the first importance to determine its integral weight. The weight of a litre of hydrogen gas (H₂) at 0° and 760 m.m. being approximately 0.0896 grm., and that of a litre of water at 100° (its temperature of formation at 760 m.m.) 958.78 grms., we have:—

$$0.0896 : 958.78 :: 2 : x = 21400.3.$$

Taking Regnault's figures for hydrogen = 0.089578 grm., the weight of a litre of water vapour (H₂O = 17.96) calculated for the same temperature and pressure = 0.8044 grm.; we have then:—

$$0.089578 : 958.78 :: 2 : x = 21406.6$$

$$0.8044 : 958.78 :: 1 : x = 1191.9$$

* "A New Basis for Chemistry," § 12.

* Read before the National Academy of Sciences, April 17, 1888. Reprinted from the *American Chemical Journal*, vol. x., No. 5.

† Hannay and Hogarth, *Proc. Roy. Soc. Lond.*, xlix., 324, and *CHEMICAL NEWS*, xii., 103-106; also, "A New Basis for Chemistry," 2nd Edition, §§ 120, 121.

Of these the last equation gives the coefficient of condensation for water, and if, rejecting the fraction, we assume water to be $1192(\text{H}_2\text{O})$, we have $1192 \times 17.96 = 21408$. In the uncertainty which still prevails as to the exact weight of oxygen, hydrogen being unity,* we may safely assume in the calculation of their integral weights from the observed densities of other liquid and solid species, the first-found number, or 21400, as a sufficiently close approximation to the integral weight of water.

21. As regards the further history of the views just stated, it was pointed out in the first edition of the author's "New Basis for Chemistry" (§§ 66, 67) that in applying to water the well-known formula for calculating the so-called atomic volume, $p \div d = v$, while d is its density at 4° , which is the unit of specific gravity for liquids and solids, p is the equivalent weight of its vapour, which is also its density, hydrogen being the unit. Hence the relation of $d:p$ involves the relation of the density of water to that of its vapour, and finally to that of hydrogen gas; and thus enables us to determine the amount of contraction of H_2O in passing from the gaseous to the liquid state, or, in other words, its coefficient of condensation, v being the reciprocal of this coefficient. It was then said, "the question to be settled in fixing the equivalent weight of water is to know its specific gravity as compared with hydrogen gas, or with steam."

In applying this method, the density of steam at 100° as compared with water at 100° having, for the reasons given, occupied the writer's attention, he, by inadvertence, took the densities at this temperature, and was thus led to assign to water the erroneous formula, $1628(\text{H}_2\text{O})$, which, assuming $\text{H}_2\text{O} = 17.9633$, gave an integral weight of 29244. In resuming, however, in §95 of the same volume, the question of the density of liquids and solids taken with water at 4° as unity, it was declared to be "necessary to refer them to a common standard of density, or, in other words, to determine the relation of density between water and hydrogen gas"; d being "the density of water at 4° , and p that of hydrogen at 0° ." Soon after in the paper on "Chemical Integration" referred to in §20, it was said that "instead of the weight of atmospheric air at 0° and 760 m.m. . . . as the standard unit of specific gravity for all gases and vapours, hydrogen at the same temperature, which gives us the unit of integral weight, would seem to be the natural unit of specific gravity for all bodies whatsoever"; and again, in comparing the densities of liquid and solid species "with the density of the hydrogen unit, H_2 , we get the specific gravity of these bodies, the diad integer of hydrogen at 0° and 760 m.m. being unity." Still further, in the second paper cited in §20, it was said, "hydrogen, as the lightest known species, is the unit of integral weight in chemistry, and a litre of this gas at 0° and 760 m.m. being assumed as a unit of volume for all species, the weight of a litre of any other vapour or gas at the standard temperature and pressure is its integral weight"; while the weight of the same volume for liquids should be taken "at the temperatures at which they are generated by the metamorphosis, through condensation, of the corresponding gaseous species." "In like manner, the weight of solids should, theoretically, be determined at the temperatures at which they are generated by the metamorphosis of gaseous or liquid species"; in other words, we should take for any solid species "the weight of the same volume at the highest temperature at which that species can sustain without undergoing a change of state." Notwithstanding all these repeated statements, the erroneous value for the integral weight of water, calculated by comparing hydrogen gas, water vapour, and water itself, at the common temperature of 100° , was, by an oversight, retained until corrected by the writer in a note on "The Integral Weight of Water" in the *London, Edinburgh, and Dublin Philo-*

sophical Magazine for April, and in the *American Journal of Science* for May, 1888.

22. In the paper on "Integral Weights in Chemistry" was, moreover, considered at some length the relation of the regular thermic changes in volume alike of water and of most solid species to the question of integral weights and specific gravities. It follows from what has been said above that, theoretically, the weight of the volume of water should be taken at 100° , and that of most solids, such as metals, ores, gems, and spars, at temperatures much more elevated. But we have sought to show by comparison of the cubic expansion of water between 4° and 100° , with the much smaller rates of expansion of the solid species in question between 4° and the temperatures of their chemical change by heat, that the resulting errors in the determination of specific gravities at ordinary temperatures to a considerable extent balance each other, and further, that the imperfections and impurities of most natural and artificial species introduce in such determinations "possible deviations in the one and the other direction as great as those due to the different rates of expansion of water and these species, so that we may take the approximate specific gravities got with water at 4° (or better at 15.5°) as an available basis for fixing the integral weights of most solid species."

23. To illustrate alike the mode of calculating the integral weights of solid species, and the use and inter-relations of the two standards of specific gravity mentioned above, namely, water at ordinary temperatures and hydrogen gas at 0° and 760 m.m., we may take the case of a crystalline species formed by the condensation of an unknown number of volumes of a theoretical calcium carbonate, $\text{CCaO}_3 = 100$. The integral weight of water being in round numbers (§ 20) 21,400, and the specific gravity of the calcareous species (water 1'000) 2'730, we have—

$$21,400 \times 2.730 = 58,422.$$

Dividing the integral weight thus found by that of $\text{CCaO}_3 = 100$, we find the number of volumes of this hypothetical carbonate condensed in one volume of the calcareous species, or, in other words, its coefficient of condensation, to be 584.22. Rejecting the fraction, we have for this species, which is calcite, $584(\text{CCaO}_3) = 58,400$. with a theoretical specific gravity of 2'729.* The relation between the integral weight of the calcium carbonate, $\text{CCaO}_3 = 100$ (hydrogen = 1.0, being unity), and the specific gravity of the calcite (water = 21,400, being unity), is got by the equation—

$$2.729 : 100 :: 1 : x = \frac{p}{d} = v = 36.643.$$

This, the so-called molecular or atomic volume of CCaO_3 as it exists in calcite of such density, is the reciprocal of the above coefficient of condensation, since—

$$36.643 \times 584 = 21399.5.$$

But calcite of this density is 58,400 times heavier than the same volume of hydrogen at 0° and 760 m.m., so that, substituting this value (its specific gravity on the hydrogen basis (for the first term in the above equation, we find the value of v ($\text{H} = 1.0$) to be = 0.0017123, and we have—

$$1 : 21,400 :: 0.0017123 : 36.643.$$

In like manner, water, $1192(\text{H}_2\text{O})$, taking itself as the unit of specific gravity, gives $v = 17.96$, while on the hydrogen basis, with an integral weight of 21,400, we find $v = 0.000839$ nearly. But $1192 \times 0.000839 = 1.00088$.

23. In considering, in 1863, the question of differences in condensation, as exemplified between the various carbon spars, hornblende and pyroxene, fibrolite and cyanite, and especially between meionite and zoisite, it was said, "the augmentation in density, in hardness, and

* Vide "The Relative Values of the Atomic Weights of Hydrogen and Oxygen." Cooke and Richards, *American Chemical Journal*, x., 81, and *Proc. Amer. Acad.*, 1887, xxiii.; also Rayleigh, *Proc. Roy. Soc. London*, 1888, xliii., 356.

* The equivalent weight of CCaO_3 is here calculated with $\text{O} = 16$, substituting for which the value $\text{O} = 15.96$, we have instead of 100 the number 99.88. This gives for 584CCaO_3 , instead of 58,400, an integral weight of 58,330, corresponding to a specific gravity of 2.7357 instead of 2.7290, a difference so small that it may be neglected as within the limits of error.

in chemical indifference which is seen in this last species [as compared with meionite] is doubtless to be ascribed to a more elevated equivalent, or, in other words, to a more condensed molecule.* Again, in 1867, in discussing these and other examples in mineral species, it was said, "the hardness of these isomeric or allotropic species, and their indifference to chemical reagents, increase with their condensation, or, in other words, vary inversely with their empirical equivalent volumes, so that we here find a direct relation between chemical and physical properties."† The conclusion then reached was, in fact, that for related solids, hardness and chemical indifference increase with the condensation of the species, or, in other words, vary *inversely* as their empirical equivalent or so-called atomic volumes, represented by v :—

$$\frac{\text{atomic weight}}{\text{specific gravity}} = \text{atomic volume} = \frac{p}{d} = v.$$

This is in accordance with the earlier observations as to the tenacity and hardness of metals and alloys. Wertheim, from his experiments, concluded (as Guyton Morveau had long before) that the order of the common metals for tenacity and for hardness is practically the same, and announced in 1841 that the tenacity varies *directly* as the quotient of the specific gravity divided by the atomic weight :—

$$\frac{\text{specific gravity}}{\text{atomic weight}} = \frac{d}{p} = \frac{1}{v}.$$

This conclusion was confirmed by the studies of Calvert and Johnson, in 1859, on the hardness of metals and alloys; by those of Karmarsch on the tenacity of metallic wires; and by those of Bottone, in 1873, also on the hardness of metals; the latter maintaining that for homogeneous bodies of uniform texture, hardness and tenacity vary together in accordance with the law enunciated by Wertheim.‡ The law thus arrived at by various investigators for the hardness and tenacity of metals and alloys is identical with that independently deduced by the author, not only for the hardness but for the indifference to chemical changes, of related silicates, carbonates, and oxides.

24. We have sought in the preceding pages to set forth and to explain what may be regarded as the fundamental facts of chemistry, by an extension of the well-known and verified laws of combination by weight and volume. In doing this it has not seemed necessary or in any way advantageous to invoke the aid of the atomic hypothesis. This, which was adopted in 1808 by Dalton to explain the facts of definite and multiple proportions observed in chemical changes, has since been greatly extended and modified in the effort to apply it to many phenomena then unknown. Molecules being assumed to be built up of atoms, it is supposed, in the language of Lothar Meyer, one of the most able and learned exponents of the hypothesis, that while "each monovalent atom possesses only a single position in space by which another atom can be held by it in stable equilibrium," the polyvalent atoms may have "four, five, or six such positions," or points in space. The atoms themselves "are in a state of active motion, with these points as centres of equilibrium. The motion may be rotary or oscillatory. In those cases in which an atom fills two or more of these points it is considered to oscillate between, or, rotating, to pass through these centres." These atoms are furnished with "bonds," "links," or "hooks," and are joined together by various modes of "atomic linking" both single and

double, forming "rings," "chain-like groups," "open chains," "closed chains," "branched chains," &c. Thus, for example, "a branched series of atoms is obtained, composed of several linear chains. In the same way these branches can also divide, and the new branches may be united together by connecting links, forming ring-like or net-like structures." The author, however, tells us in a footnote that the expression "ring-shaped" "need not be accepted as applying to space; it only indicates that the attractions between the atoms which maintain the coherence of the molecule form a continuous series."*

In like manner Prescott states that "in the use of the chemical term, position," he will be understood to refer "not to arrangement in space, but to the order of the union of the atoms with each other."† Another distinguished American chemist has, however, lately assured us that the question of "atom-grouping has a mechanical as well as a chemical side," and, notwithstanding the provisos above quoted, it seems impossible to divest the language which we have quoted from Lothar Meyer of a geometrical sense. Without speaking of the fancies of earlier writers as to the architecture of molecules, it is well known that Le Bel and Van't Hoff have speculated upon the supposed arrangement of the atoms of molecules in space, and that Wislicenus has lately made a further contribution in the same direction towards a hypothesis of the geometry of molecules.‡

25. By such assumptions as the foregoing the modern atomistic chemistry seeks to explain the physical and chemical characters of species, which it regards as dependent upon forces and properties supposed to dwell in the individual atoms from which these are conceived to be built up. Structural formulæ in accordance with this hypothesis may serve to explain the facts of definite and multiple proportions, of polymerism in vapours, and of the peculiar differences presented by such isomeric bodies as the primary, secondary, and tertiary alcohols, $C_nH_{2n+2}O$. Assumed differences in "the order of the union of atoms with each other" may be made to account for the unlike genetic relations presented in their chemical changes by certain of these isomeric species, but there are other phenomena which it will require still further and purely gratuitous assumptions to explain by the atomic hypothesis. Such, for example, are the subtle differences which divide the amylic alcohol got by fermentation into two species, one optically active and the other inactive. These, though convertible the one into the other, present also minor chemical distinctions, and, moreover, transmit their optical characters to the derived valeric acids.§ Similar chemical and optical unlikenesses appear in the limonenes, pinenes, and camphenes, which are all apparently isomers of dipentene; and other examples of optical, crystalline, and chemical differences meet us frequently in the study of isomeric and homologous bodies, which can hardly be explained by any constitutional or so-called structural formulæ.

To indicate the essential differences which distinguish two substances having, it may be, the same centesimal composition and the same density, alike in the vaporous and the liquid or solid state, as in the instances above noted, they have been said by different writers to be unlike in "structure," or in "organisation." The term structure, however, implies that the substance in question is put together or is built up by a certain arrangement of parts, while the term organisation superadds the conception of such a subordination of parts to function as belongs to crystalline or to biotic structures. For these

reasons it is conceived that the term "constitution," which implies no mechanical hypothesis, but simply refers to the character or the *essential form* of the species in question, is to be preferred. Chemical species are subject to constitutional changes, or, in the language of Andrews, to "internal disturbances," which alter to greater or less degrees alike their dynamical and their chemical relations. Such constitutional changes may manifest themselves in veritable metamorphosis by homogeneous integration or disintegration, and consequent change in integral weight; or in other cases by such slighter differences as have been signalled in the amylic alcohols and the various dipentines; or as are seen in certain cases of crystalline dimorphism, which are apparently independent of any change in density. Were it possible to establish on valid grounds the existence of chemical molecules, built up by the putting together of the atoms in the fantastic arrangements supposed by the present highly complicated atomic hypothesis, further assumptions would still be required to account for these minor constitutional differences. Something radically different from this or any other mechanical hypothesis must, in the writer's opinion, be devised before we can hope to explain adequately the dynamical and chemical history of matter. Signs are not wanting that this famous hypothesis, so generally accepted by chemists since Dalton's time, is felt by many to be no longer adequate, and that, in the language of J. P. Cooke, it may be regarded as "only a temporary expedient for representing the facts of chemistry to the mind.*" The fate which befell the corpuscular hypothesis of light, and now seems to menace the undulatory hypothesis, appears to await the atomic hypothesis in chemistry.

THE ACTION OF CHLORINE ON THE LIGNO-CELLULOSES.

By C. F. CROSS and E. J. BEVAN.

WE have recently made a quantitative study of the chlorination of the ligno-celluloses, using a method and apparatus which may be found to have other application in cases in which it is required to determine the volume of a gas disappearing in combination. We anticipate the publication of the particular results of this research by the following brief description of the apparatus and method.

A is the flask or bottle in which the reaction takes place. It is closed by a cork (of indiarubber well coated with paraffin) through which pass two tubes, the first of narrow bore, bent at right angles, carrying a stop-cock, and serving to connect the flask with the measuring apparatus; the second is a piece of wide tubing, blown out below to a relatively large and thin-walled bulb. Into this bulb the fibre, suitably prepared, is introduced. Outside the cork a piece of rubber tubing is passed over the extremity of the tube, and through this a piece of rod, of somewhat less diameter than the tube, is pushed until it presses upon the fibre in the bulb.

B is a tube containing a substance capable of combining with chlorine—*e.g.*, a small quantity of the fibre itself—inserted between the flask and measuring apparatus, serving to indicate any transfer of chlorine from the flask by diffusion, should such take place; this, however, we have not found to occur.

The bottle is filled with chlorine by displacement over water, inverted, and the cork carrying the bulb-tube with the fibre is inserted; the stop-cock on the other tube is closed and the connection made as in the figure. When the bottle has attained the temperature of the room the levels in the measuring apparatus are adjusted to the lowest graduation of the instrument, with both stop-cocks open. The stop-cocks are then closed, and the bulb in the reaction flask is broken by pressure on the rod. The

latter is opened, and mercury is continuously run in to keep pace with the movement in the right hand limb of the measuring apparatus, which corresponds with and measures the chlorine disappearing.

Such a method is open to obvious sources of error, the chief of which is the *absorption* of chlorine by the fibre and the water which it contains. The volume disappearing in combination, on the other hand, is relatively large; *e.g.*, in one experiment in which 1 grm. of jute was taken it

amounted to 60 c.c. (at 18° and 758 m.m.). That the method is trustworthy is shown by the satisfactory agreement of the numbers in a series of experiments, and further by the coincidence of these numbers with those calculated from the HCl formed (and determined by titration).

The results obtained have thrown light on the molecular constitution of the ligno-celluloses, and will be discussed in a paper about to be communicated.

SILICON HYDRIDE.

By H. N. WARREN, Research Analyst.

REQUIRING a somewhat large quantity of amorphous silicon, I made use of the following ready method of preparing the same, namely, by the action of gaseous silicon fluoride upon metallic magnesium, contained in an ordinary combustion tube, and heated by the aid of a gas flame. The products being amorphous silicon, magnesium fluoride, and a small quantity of a peculiar form of magnesium silicide, which, when exposed to the action of the more concentrated acids, and especially hydrochloric, evolved a most spontaneously inflammable silicon hydride; this, when in contact with the atmosphere, takes fire with explosive violence, the nature of its combustion resembling in every respect that of phosphorated hydrogen.

* American Journal of Science (1883), xxvi., 310 to 316.

The same gas may, however, be obtained free from spontaneous inflammability by reacting on the above-mentioned compound with the weaker acids, such as acetic and oxalic, but the difficulty arising from freeing it from uncombined hydrogen gas renders it impossible to speak definitely, although from various experiments that have been performed with the same, it would appear to be closely allied to hydric phosphide, and to be a mixture of silicon hydride, both in the gaseous, liquid, and solid form.

SELECTIVE ABSORPTION OF METALS FOR ULTRA VIOLET LIGHT.*

By JOHN TROWBRIDGE and W. C. SABINE.

THE question of the absorption of the ultra violet rays by metallic surfaces possesses considerable interest, both from a practical and a theoretical point of view. By the kindness of Prof. Pickering, Director of the Harvard University Observatory, we were provided with a number of metallic surfaces prepared by Prof. Wright, of Yale College. These metallic surfaces were deposited upon glass by means of electricity. The surfaces were of gold, platinum, tellurium, palladium, copper, silver, and steel. A preliminary trial had shown us that a heliostat mirror of the same composition as that upon which the grating was ruled did not absorb light of greater wave-length than 2900. We resolved, therefore, to compare other metals with speculum metal. Since our heliostat arrangement required two mirrors to direct the light upon the slit of the spectroscopic, we employed a speculum mirror for the movable mirror of the heliostat, and replaced the fixed mirror by mirrors of the metals whose selective absorption we wished to compare with that of speculum metal. To our surprise the metallic mirrors of gold, copper, nickel, steel, silver, tellurium, and palladium all reached the same limit as speculum metal. Here was a complete experimental proof that colour in no way influences the selective absorption of metals for the ultra violet rays; for the copper mirror, which gave a strong yellow light by reflection, was as capable of reflecting light of as short wave-length as the brilliant white surface of polished silver. Although the metallic surfaces we employed were bright, slight differences in polish undoubtedly existed, and therefore we are not justified in placing much reliance upon the evidence presented by the intensity of the photographs of the solar spectrum obtained by light reflected into the spectroscopic by these various metallic surfaces. The photographs, however, can be classified according to intensity in order of numbers as follows:—number 1 indicating the greatest intensity: 1, steel; 2, gold; 3, platinum; 4, palladium; 5, silver; 6, tellurium; 7, copper.

It was evident from these experiments that the selective absorption of metals is far less than the absorption exercised by the earth's atmosphere. We therefore resolved to employ the light of the electric spark between metallic terminals, in order to ascertain whether any limit of absorption could be reached. For this purpose, the light of the spark between copper terminals was reflected, by means of a mirror of the metal whose selective absorption we wished to examine, upon the slit of the spectroscopic. To protect the surface of the mirror from the effects of the spark, a thin plate of quartz was placed in front of it. It was found that the copper mirror showed no limit of selective absorption by reflection for wave-lengths of light produced by burning copper at the limits of the copper spectrum, that is, at wave-length 2100. The photographic plate taken by this method showed all the

lines that the plates showed which were taken by the direct light of the spark unreflected and unabsorbed by any medium. The palladium mirror was substituted for the copper mirror, and also showed no limit of selective absorption above wave-length 2100. We are led to conclude, therefore, that the metallic surface of the speculum metal upon which the lines are ruled which form the diffraction grating does not fix by selective absorption the limit of metallic spectra at 1800 to 2100. This limit more likely resides in the materials forming the sensitive emulsion with which the sensitive plates are coated. We have found that a marked difference exists in different emulsions in regard to sensitiveness to ultra-violet light. The various staining processes, which enhance to such a marked degree the sensitiveness of photographic plates to wave-lengths of greater length, do not seem to affect the limit of metallic spectra in the ultra-violet. Thus, plates stained with erythrosine, which are extremely sensitive to yellow and green light, continue to give the same limit in the ultra-violet after staining as they did before they were submitted to the staining process.—*Proceedings of the American Academy of Arts and Sciences.*

THE ESTIMATION OF QUININE BY KERNER'S METHOD.

By EDSSEL A. RUDDIMAN.

(Continued from p. 204.)

(3) *Experiments to Determine the Accuracy of Kerner's Figures.*—For the quantitative estimation of cinchonidine sulphate in quinine sulphate by his ammonia test, Kerner* gives figures obtained for the fraction of 1 c.c. of water of ammonia, sp. gr. 0.920, which 1 m.grm. of cinchonidine requires to dissolve it, varying from 0.288 to 0.350 c.c. His method of experimentation in brief is as follows:—To 50 c.c. of standard quinine sulphate solution, prepared by digesting chemically pure quinine sulphate in water at 15° C., and filtering, he adds a weighed quantity of cinchonidine sulphate, varying the amount added. This solution, in portions of 10 c.c., is then titrated with ammonia water of sp. gr. 0.920. Simultaneously with this, 50 c.c. of the standard solution are titrated in portions of 10 c.c. each. The excess of ammonia used in the former case over that used in the latter is divided by the number of m.grms. of cinchonidine sulphate contained in 10 c.c. of the former solution. This will give the amount of ammonia water necessary to dissolve 1 m.grm. of the cinchonidine salt. According to this method I made twenty-five experiments as given below, varying the amount of cinchonidine sulphate from 0.005 grm. to 0.05 grm. for every 50 c.c. of the standard solution.

Three experiments (I., VIII., XIII.) were made to find the number of c.c. of the ammonia water taken by the standard quinine sulphate filtrates alone. This number of c.c. was deducted from the reading in each following experiment with cinchonidine addition; thus the 6.385 c.c. obtained in I. was deducted from the readings in experiments II. to VII. for the calculations to give the figures of the last column.

In each experiment I took the average of four titrations; then taking the average of the twenty-five experiments, covering one hundred titrations, I found that for every m.grm. of cinchonidine there was required 0.360 c.c. of ammonia water of sp. gr. 0.920 to dissolve the precipitate. In the following experiments the temperature of the resulting solution of each titration was taken as soon as the titration was completed. When the temperature thus taken varied from 15° C., due allowance was made by

adding or subtracting for every degree of increase or decrease, as the case might be, 0.148 c.c. to or from the amount of ammonia used. In order to secure constancy in composition of the cinchonidine salt taken, the cinchonidine sulphate was exposed to the air until thoroughly effloresced and then weighed as having the formula $(C_{19}H_{22}N_2O)_2H_2SO_4 \cdot 2H_2O$. From this the equivalent quantity of the crystallised salt ($6H_2O$) was calculated. The following abbreviations are used in the table below:— S. Q. S. S. for standard quinine sulphate solution; am. for ammonia water; ef. cin. sulph. for effloresced cinchonidine sulphate.

Taking the average result of the twenty-five experiments I found that 1 m.grm. of cinchonidine sulphate $[(C_{19}H_{22}N_2O)_2H_2SO_4 \cdot 6H_2O]$, when dissolved in a solution of quinine sulphate, requires 0.36 c.c. of ammonia water of sp. gr. 0.920 to precipitate and re-dissolve it.

(4) *Method for Quantitative Estimation.*—Kerner's* method and claims for the quantitative estimation of cinchonidine sulphate in commercial quinine sulphate are here given in a faithful translation as follows:—Five grms. of the salt to be examined are rubbed in a mortar with distilled water to a homogeneous mass, then transferred to a stoppered flask, rinsing with enough water so that in all 50 c.c. are used. The mixture is then either placed in water (of about 50° C.), shaken vigorously and cooled, or digested without heating for twelve to eighteen hours, shaking vigorously and frequently. The flask is now placed in cold water, together with the mixture of standard quinine and water for comparative titration and the ammonia water, and when all are at the same temperature the quinine solutions are filtered through dry filter papers. The temperatures of the air and water taken into consideration in the operation lie between 12° and 24°. For the absolute numerical titre they are not indifferent, but for the relative result they are. The preservation of a fixed low temperature is not necessary if the standard quinine solution is prepared and filtered at the same temperature. As a measuring instrument for the ammonia, a long burette finely divided (1—20 c.c.) is used. The saturated quinine sulphate solution is measured with an exact 10 c.c. pipette into a test-glass, and the titration is carried on as follows:—5 c.c. of ammonia water are added from the burette to 10 c.c. of quinine solution, the test-glass then closed with the finger and gently turned two or three times without shaking. The greater part of the quinine is now precipitated and re-dissolved, but the fluid is still distinctly turbid. The ammonia is now added in small portions (3—10, 2—10, 1—10 c.c.), and each time after gently turning it is observed whether complete clearing follows or not. On each addition of the ammonia it is well to wait five or ten seconds before adding more. After some experience the end reaction—the complete clearing up of the solution—may be discerned with great accuracy. If 5 grms. of the sulphate are treated with 50 c.c. of water, and 40 c.c. filtrate be obtained, there will be sufficient to make four titrations, of which the average result may be taken. The simultaneous titration of the standard quinine solution gives the exact titre of ammonia, and the excess used over this to obtain the solution of the quinine sulphate under examination indicates the amount

of cinchonidine present more exactly than is determined by any gravimetric method. As seen from the analytical results (Kerner's), 0.288 c.c., or in round numbers 0.3 c.c., of ammonia water sp. gr. 0.920 corresponds to one m.grm. of crystallised cinchonidine sulphate in one grm. of the sulphate of quinine tested. And as the possible mistake in observation amounts to only 0.1 c.c., or at the highest 0.15 c.c., closer readings could hardly be wished for than those of the titration method, while an error of more than 1.30 per cent to 1.20 per cent does not need to happen. It is to be observed that the examination of only the quinine sulphate, which passes the definition of the official test, or rather that which does not contain more than 1—1.5 per cent of cinchonidine sulphate, is taken into consideration. If an aqueous mixture in the proportion of 1:10 be prepared from a sulphate of quinine containing more than 2 per cent of cinchonidine sulphate, the estimation is inaccurate because the filtrate then contains so large a proportion of foreign alkaloids that the end reaction is obscured. The addition of the ammonia in such a case causes either a large flaky precipitate difficult to re-dissolve, or, during the addition of ammonia near the point of clarification, a greater turbidity suddenly occurs, so that on standing it becomes gelatinous and on that account the end reaction is not distinct. This inconvenience is entirely avoided if, after noting the kind and intensity of the turbidity by the qualitative test, either the 1:10 prepared mixture is diluted with a definite amount of standard quinine solution, or, if a higher proportion of water be used in the preparation of the saturated solution, 1 part of the salt to 50, 100, 200, &c., parts of water.*

Mention has been made of the fact that, by digesting commercial quinine sulphate in 10 parts of water at 15° C., the cinchonidine sulphate is not all dissolved. Now since by digesting it at a warmer temperature the filtrate indicates a higher per cent of cinchonidine; to estimate as nearly as possible the amount of cinchonidine, all of the quinine should be dissolved. It seems then as though Kerner's method of estimation should be modified so that all of the salt shall be dissolved. This may be done by digesting the quinine sulphate in 30 parts of water at 100°, cooling, digesting at 15° for two hours, and filtering. To portions of the filtrate apply the test as given by Kerner. In calculating the amount of cinchonidine sulphate, allowance must be made for the dilution caused by using 30 c.c. instead of 10 c.c. of water for digestion. It is not claimed that all of the cinchonidine is estimated by this method, for no doubt some of it crystallises out again with the quinine. Hesse says that two crystallisations are necessary to remove all of the cinchonidine, while others maintain that four or five crystallisations are necessary.

In working with one sample of commercial quinine sulphate I estimated the amount of cinchonidine sulphate according to Kerner's method, and found the indication to be 1.2 per cent. In using the same proportion of the salt and water, but by digesting at 100°, then cooling, digesting at 15°, and filtering on adding ammonia water, the end reaction could not be determined accurately on account of the gelatinous precipitate which forms when there is much over 2 per cent of cinchonidine sulphate present. Now on treating a portion of the same sample with 30 parts of boiling water, cooling, digesting at 15°, filtering, and applying the test, it indicated 6.3 per cent of cinchonidine sulphate present in the quinine sulphate.

In working with a sample of quinine sulphate made by another manufacturer, according to Kerner's method of estimation, that is by digesting the salt with 10 parts of water at 15°, the result indicated 2.2 per cent cinchonidine. When the same salt was digested with 30 parts of boiling water before applying the test to the filtrate, an indication of 5.9 per cent of cinchonidine sulphate was obtained.

(To be continued).

* This report of Dr. Kerner in 1880 is presented at length because it does not appear to be accessible in our language.

NOTICES OF BOOKS.

A Class Book of Elementary Chemistry. (Clarendon Press Series). By W. W. FISHER, M.A., F.C.S., Aldrichian Demonstrator of Chemistry. Oxford: Clarendon Press.

THIS is one of the numerous elementary scientific treatises which are a source of perplexity to the reviewer. It would be a hard task to find anything here to which objection might be taken without a degree of hypercriticism. On the other hand it would be no less hard to discover any well-marked advantage which the class-book before us possesses as compared with others of its kind. To us it seems that until some important step in the fundamental principles of the science has been taken there is no room for any more manuals or handbooks.

Outlines of Qualitative Analysis. By A. HUMBOLDT SEXTON, F.I.C., F.C.S., F.R.S.E. London: C. Griffin and Co.

AUTUMN generally brings with it a crop of elementary works on chemistry whose *raison d'être* it is not always easy to discover. The author, admitting that existing manuals of analysis are not few, divides them into two classes. On the one hand there are treatises like those of Fresenius, Rose, and others, intended principally as works of reference for the advanced student and the professional analyst. On the other there are small books adapted to some "syllabus," and religiously avoiding whatsoever lies outside such limit. Between these two extremes the author endeavours to steer a middle course.

Professor Sexton has the good sense not to follow any syllabus in the preparation of his book, but he points out certain sections to which students preparing for the examinations of the "Department" may confine their attention.

CORRESPONDENCE.

ANCIENT MORTARS.

To the Editor of the Chemical News.

SIR,—The short but interesting paper by Mr. John Spiller, F.C.S., in the *CHEMICAL NEWS* (vol. lviii., p. 189) on the "Ancient Mortar from the Roman Wall of London," raises a question of some theoretical importance. The remarkable occurrence of nearly 11 per cent of soluble silica in this mortar and in that of the Roman bath at Bath, suggests certainly the possibility of the synthesis of silicate of lime by simple saturation of the ingredients with water during a space of some eighteen centuries. Now we know that silica, which is so inert a body under ordinary physical conditions, is at high temperatures one of the most potent bodies in nature; and silicate of lime can be formed by fritting together lime and clean quartz sand. I have seen specimens of wollastonite which were made some years ago in this way in Dr. Percy's laboratory. But have we any right to infer from this the probability of its formation under the circumstances described in the paper referred to? I think not. It seems far more likely that the soluble silica occurred in the form of easily-decomposable silicates, which are found in a more or less vitreous condition in the pumiceous tuffs (such as *possuolana*), which are extensively worked for "hydraulic mortar." But we need not suppose such materials to have been imported from Italy. They are formed much nearer home in the *trass* of the Brohlthal and the Nettetthal in the Vorder Eifel. That the Romans were familiar with such a use of the material in question we know from the writings of Strabo. The city of Pateoli "had artificial wharfs for ships, for the construction of which the sand of

the place, mixed with lime, is remarkably adapted from its speedy solidification." The *trass* of the Vorder Eifel has been worked for centuries, and transported in barges down the Rhine to Holland, where it is used for purposes similar to that mentioned by Strabo; and what we know of the engineering capacities of the Romans leads to the belief that they would have recognised the value of the *trass* for such purposes. Is it not possible that the material may have been brought thence to London, and even to Bath?

If Mr. Spiller were to obtain the aid of a competent petrologist or mineralogist in the microscopic examination of his HCl residues, some new light might be thrown on this interesting question.—I am, &c.,

A. IRVING.

Wellington College, Berks,

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Bulletin de la Société Chimique de Paris.
Vol. xlix., No. 12, June 20, 1888.

Researches on Porcelains known as "Craquelées."—C. Lauth and G. Dutailly.—This paper, though evidently of great importance to the porcelain trade, does not admit of useful abstraction.

On the Various Modes of Explosive Decomposition of Picric Acid and Nitro-compounds.—M. Berthelot.

The Graduation of Tubes intended for Gazometric Measurements.—M. Berthelot.

On the "Collection of Ancient Greek Alchemists."—M. Berthelot.

Metallic Arsenic known to the Ancients.—M. Berthelot.—These papers have been already noticed.

Decolouration of Tincture of Litmus in Closed Vessels.—M. Dubois.—It is known that tincture of litmus kept in a closed vessel soon turns paler, and is completely decolourised, the blue colour reappearing on exposure to air. On microscopic examination it is found that the tincture contains a Flora and a Fauna consisting of infusoria, zoospores, algæ, fungi, in short, microbia of different species. To ascertain if these organisms were not the efficient agents in the decolouration of the tincture, the author placed, on February 15th, three samples of tincture of litmus, all from the same source, in three glass bottles. Two of the bottles were sterilised, the one by mercuric chloride, the other by heat, and both were sealed at the lamp. The third bottle was merely sealed, and all three contained a small store of air. The specimen in the non-sterilised vessel quickly lost its blue tint, and became of a vinous red, and by May 1st it was completely decolourised. In the other bottles, though exposed to the light, the blue colour did not vary. The microbe to which this change is due is a very small micrococcus, generally found arranged in groups of four.

Vol. I., No. 1, July 5, 1888.

Researches on Drainage.—M. Berthelot.

On Certain General Conditions of the Fixation of Nitrogen by Vegetable Soil.—M. Berthelot.

The Condition of Potassa in Plants, in the Earth, and in Vegetable Soil, and on its Determination.—MM. Berthelot and André.

On Phosphorus and Phosphoric Acid in Vegetation.—MM. Berthelot and André.

The Condition of Sulphur and Phosphorus in Plants, in the Earth, and in Soils, and on their Determination.—MM. Berthelot and André.

The Absorption of Saline Matters by Plants.—MM. Berthelot and André.—The subject-matter of these memoirs has been already noticed.

Action of Hydriodic Acid upon Allyl Iodide.—H. Malbot.—The author concludes that in this reaction there is the preliminary formation of a large quantity of propylene iodide, which iodide, under certain circumstances, may either be converted into isopropyl iodide without a liberation of propylene, or may be split up into propylene and iodine without formation of iodine and isopropyl. Thus, the ultimate product of the transformation of allyl iodide may be either isopropyl iodide or propylene.

The Crystalline Water of the Alums.—MM. Lescœur and Mathurin.—Alums are generally considered as containing twenty-four equivalents of crystalline water. This is contested by M. Maumené, who ascribes to potassium alum as much as twenty-nine equivalents. M. de Boissieu has undertaken to re-determine the crystalline water of potassium and chromium alums, and has obtained results ranging between 23.6 and 24.1 equivs. As the methods which he employed seemed open to objection, the authors have taken up the question anew, and conclude that the products analysed contain 24 equivs. of water. Further researches proved that the specimens analysed were not mixtures, but perfectly definite compounds not altered by efflorescence.

Remarks on the Observations of M. Maumené.—J. M. Crafts.—M. Maumené declares that a method for purifying mercury, given in the *Bulletin* (vol. xlix., p. 898), had been previously indicated by Berzelius, and afterwards by himself. In the passage cited Berzelius says merely that he had obtained a plumbous oxide by dissolving lead in mercury through which was passed a current of air, but he does not recommend the process for the purification of mercury, either in his contribution to the *Annales* (? *Annalen*), or in his treatise on chemistry. The writer admits that M. Maumené has the priority as regards the principle of the purification of mercury by agitation with air. He conceives, however, that he has suggested a more convenient means of carrying out the process than that proposed by M. Maumené.

The Compound Nature of the Elements.—E. Allary.—In support of his hypothesis on chlorine and cyanogen *Bulletin* (May 20, 1888), the author cites Victor Meyer as having partially decomposed chlorine into oxygen and an unknown substance (?). The experiment of Meyer is described in full in a memoir by Sir B. Brodie, which may be found in the *Moniteur Scientifique* (1880, p. 539). The memoir of M. Lockyer (*Moniteur Scientifique*, March, 1879) likewise proves the compound nature of certain elements.

Determination of Para-nitrotoluene.—F. Reverdin and Ch. de la Harpe.—The authors first prepare an absolutely pure ortho-nitrotoluene, and effect the determination as follows:—They sulphurise the nitrotoluene in question and a nitrotoluene containing exactly 4 per cent of the para-compound. They pour the product of the sulphonation into water, dilute to 200 c.c., and compare the colour reactions which 1 c.c. of each of these liquids yields with 5 c.c. of a solution of caustic soda at $\frac{1}{10}$. If the sample gives a redder colour we take a measured quantity of it (20 or 50 c.c.) and dilute progressively until 1 c.c. of the dilute liquid, heated with 5 c.c. of the solution of soda, gives the same colouration as the standard at 4 per cent. The number of c.c. thus added to arrive at this result is noted, and we calculate to what volume the original 200 c.c. must be brought to obtain the same colouration. The authors have found by this method that the nitrotoluene of commerce contains, in general, a little more than 4 per cent of the para-compound. When operating on known mixtures of the ortho- and para-

modifications, they have always, for mixtures containing less than 20 per cent of para-, obtained results falling within 0.5 per cent of the theoretical proportions.

New General Method for the Separation and Volumetric Determination of Acids.—G. Linossier.—This method is applicable to all the acids capable of forming an insoluble compound with any of the metals precipitable by sulphuretted hydrogen. The acid is separated from the solution by causing the formation of such an insoluble compound, which is then decomposed by means of sulphuretted hydrogen, and the acid thus liberated is determined directly by acidimetry, either after the sulphuretted hydrogen has been eliminated by boiling, or by using an indicator not affected by that sulphide, such as Poirrier's orangé. The process, in case of sulphuric acid, is as follows:—The solution of sulphate, containing preferably from 0.05 to 0.1 grm. of sulphuric acid, is placed in a capsule, mixed with from 1 to 2 vols. of strong alcohol, heated almost to a boil, and precipitated with a slight excess of neutral lead acetate. The lead sulphate then collects quickly at the bottom of the capsule. When cold, the clear supernatant liquid is poured upon a filter, the precipitate is washed by decantation with a mixture of alcohol with from $\frac{1}{2}$ to 1 vol. of water, throwing the washings each time upon the filter. It is important that these liquids should only bring the smallest possible quantity of the precipitate. When the washing is completed, i.e., when a drop of the filtered liquid is no longer coloured by sulphuretted hydrogen, the funnel containing the filter is placed above a clean flask and a saturated solution of sulphuretted hydrogen is poured into the filter to convert any residual traces of lead sulphate into sulphide. The mass of lead sulphate remaining in the capsule is treated in like manner with a saturated solution of sulphuretted hydrogen, and the mixture is well agitated to ensure the complete transformation of the sulphate into sulphide. Lastly, the liquid and the lead sulphide are thrown upon the filter and washed with a solution of sulphuretted hydrogen until a drop of the filtered liquid gives no reaction with Poirrier's orangé. At this moment all the sulphuric acid is found in the free state in the filtrate. It is determined with a decinormal solution of soda after the addition of Poirrier's orangé. The method is expeditious and strictly accurate, but it is applicable only in the absence of acids capable of reacting upon Poirrier's orangé, and of precipitating salts of lead. All causes which interfere with the determination of lead in the state of sulphate (presence of free nitric acid, ammoniacal salts, &c.) interfere with the accuracy of the results.

No. 2, July 20, 1888.

The Artificial Reproduction of Hydrocerussite, the Chemical Composition of this Mineral, and the Constitution of White Lead.—L. Bourgeois.—The author's analysis of this rare mineral leads to the formula $2\text{PbCO}_3 + \text{PbO}_2\text{H}_2$. It is remarked that numerous specimens of commercial white lead have a composition oscillating between the above formula and that of neutral lead carbonate. On a microscopic examination many samples, especially those obtained by the Dutch process, are found to consist of small indefinite granules. Others, prepared by precipitating neutral lead acetate with sodium carbonate, are almost entirely formed of small and very acute prisms or double pyramids of cerussite. The white lead made by the Clichy process is almost entirely crystalline, consisting chiefly of hexagonal lamellae.

On a Hydrochlorate of Cupric Chloride.—Paul Sabatier.—The author has obtained this compound in hyacinth-red crystals, having the composition—

On exposure to air the crystals promptly lose their hydrochloric acid and leave green opaque needles. The red colouration of this hydrochlorate is an anomaly, since the salts of copper are blue or green. An analogous compound has been obtained with cadmium chloride.

Preparation of the Allyl Ammoniums by Means of Allyl Chloride and Aqueous Ammonia in Equimolecular Proportion.—H. Malbot.—The prolonged action in the cold of allyl chloride upon aqueous ammonia yields almost exclusively free triallylamine. In heat the same operation yields much tetraallylammonium in place of triallylamine. This difference arises from the free triallylamine combining with the available allyl chloride when the temperature becomes favourable. This instance must be joined to those previously given (*Annales de Chimie et de Physique*, April, 1888) to show the insufficiency of the simultaneous equations of Hofmann, and to demonstrate the gradual progression of the amines.

A Characteristic Reaction of Bismuth.—E. Leger.—The solution of bismuth iodide in potassium iodide is sometimes employed as a reagent for the detection of alkaloids, under the name of potassium iodo-bismuthate. This solution gives a fine orange-yellow deposit with a great number of organic bases; but it is a general reaction which, though very sensitive, tells us nothing concerning the nature of the alkaloid present. The author suspected that the case would be different if, instead of applying this reaction to the detection of the alkaloids, it was made to serve for the detection of bismuth. He employed to this end a reagent of the following composition:—Cinchonine, 1 part; potassium iodide, 2 parts; distilled water, 100 parts. The cinchonine is converted into nitrate, the solution is slightly heated, and the iodide of potassium is added. If this reagent is added to a solution of bismuth nitrate we obtain at once an orange yellow precipitate. The reaction is so sensitive that it shows the presence of 0.001 grm. of bismuth in a mixture of salts of copper, lead, bismuth, tin, arsenic, and antimony. It is necessary to have the reagent in excess, to avoid the presence of an excess of nitric acid. With mercuric salts the reagent gives a yellowish green precipitate, turning black if an excess of the reagent is added; with mercurous and cadmium salts a yellowish white; with silver salts an intense yellow precipitate if the reagent is in excess; with cupric salts a maroon brown precipitate; and with lead salts a sulphur yellow precipitate. This reaction cannot be used for the quantitative determination of bismuth.

MEETINGS FOR THE WEEK.

MONDAY, Nov. 5.—Royal Institution, 5. General Monthly Meeting. Society of Chemical Industry, 8. "A New Form of Polarimeter," by Mr. Heron. "Comparative Value of Antiseptics," by Mr. Kingzett.
SATURDAY, 10th.—Physical, 3. "On the Coefficient of Mutual Induction of a Helix and a Coaxial Circle," by Prof. J. V. Jones.

NAPHTHOL YELLOW.

NOTICE IS HEREBY GIVEN to Consumers, Dealers, and Manufacturers of "Naphthol Yellow" or "Fast Yellow" that such yellow colouring-matter is the subject of Letters Patent dated the 29th day of December, 1879, No. 5,305, which are the property of the Badische Anilin und Soda Fabrik, of Ludwigshafen-on-the-Rhine and Stuttgart, Germany.

The above mentioned colouring-matter can be purchased from the Badische Anilin und Soda Fabrik through their appointed Agents in Great Britain.

Messrs. SCHOTT, SEGNER, & CO., 26, Princess Street, Manchester.

Messrs. JAMES STRANG & SON, 30, Gordon Street, Glasgow
Mr. HENRY BECK, 22, Bush Lane, Cannon Street, London.

Or from their Licensees in England under the said patent, Messrs. I. LEVINSTEIN & CO., of Blackley and Crumpsall Vale Chemical Works, and 21, Minshull Street, Manchester.

Proceedings have been commenced in the Chancery Division of Her Majesty's High Court of Justice by the Badische Anilin und Soda Fabrik to restrain an infringement of this patent, and such proceedings are now pending.

The public and particularly Manufacturers and Consumers of Naphthol Yellow are cautioned that proceedings will be taken against anyone infringing the rights of the Badische Anilin und Soda Fabrik under the above mentioned patent.

J. H. JOHNSON, SON, & ELLIS,
47, Lincoln's Inn Fields, London,
Solicitors for the above named
Badische Anilin und Soda Fabrik.

A Mechanical Engineer seeks a Situation, either at home or abroad, as Assistant Engineer and Assayer. Is a good draughtsman and thoroughly well up in the Assaying of Gold and Silver Ores. Highest references and testimonials.—Address "Mail," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Situation required as Chemist or Sub-Manager in Works. Has had three years' experience of General Analysis and several as Chemist in large Sugar Refineries.—Address, "Invert," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, Assistant Chemist in Laboratory of Manure and Vitriol Works near Liverpool. State experience, age, &c., and salary required to X.K., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, Practical Man to Superintend mixing Chemical Manure; must be thoroughly acquainted with work.—Apply, Box 40, General Post Office, Leicester.

TO QUININE MANUFACTURERS AND MANUFACTURING CHEMISTS.

WIDMORE, NEAR BROMLEY, KENT.

MR. F. I. BISLEY will Sell by Auction at the Mart, City, on Wednesday, November 14, at two o'clock, the newly-erected Manufactory and Premises known as the Widmore Quinine Works, situate midway between the New Bromley and Plaistow railway stations, S. E. Railway, together with the extensive fixed and loose plant, comprising eight torpedo and balloon bark extractors, copper stills, lead tanks, air engine, air accumulator, 60 h.p. steam boiler, two steam-engines, 6000 feet one to four-inch copper, lead, and steam pipe, modern eight-inch ram, hydraulic press by Pontifex and Wood, and numerous utensils and fittings. Particulars, plans, and conditions of sale of Messrs. ELMSLIE, FORSYTH, and ELMSLIE, and of the Auctioneer, at his Offices, 63, King William Street, and Chester House, Rotherhithe.

FOR SALE.

Several STRONG CAST-IRON VESSELS, with top and bottom diaphragms, and top and bottom air-tight doors and pipe connections.

Four Wrought Iron CYLINDRICAL STILLs, with swan necks, and fitted with gauge glasses, open and closed steam pipes, &c.

LARGE COPPER CONDENSING WORM, about 350 feet long and about 4 inches diam., and Wrought Iron Tank holding the same. Also several smaller COPPER WORMS with Tanks.

AIR-PUMPS, STEAM PUMPS, Wrought-Iron AIR-TIGHT TANKS, Small Wrought-Iron CONDENSING TOWERS, &c.

Address, "Stills," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1511.

ON THE ACTION OF A PLATINUM WIRE MADE INCANDESCENT BY A CURRENT ON SOME GASES AND VAPOURS.

By Dr. W. R. HODGKINSON, F.R.S.E., and
F. K. S. LOWNDES.

PART II.

On submitting the compounds of the halogens amongst themselves to the action of the incandescent wire, previously mentioned in the case of the halogens alone, results are obtained similar to when the halogen alone is used. We find that, in the case of the halogens at least, the presence of one does not hinder the effect or action of another.

Chlorides of iodine, both ICl and ICl_3 , were operated upon, the substances being formed in the flask and then vapourised to expel air, and the current then sent through the wire. A very large flame appearance was produced, and a copious deposit of platinous salt formed on the sides of the flask, a mixture of chloride and iodide, and relatively very large crystals of platinum formed on the wires, especially on one marked B. A precisely similar result was obtained by having iodine in the flask to begin with, vapourising it, then sending in a stream of chlorine.

With bromide of iodine a similar large flame was produced and mixed bromide and iodide of platinum formed, but in this case no crystals of the metal formed on the wire.

Compounds of halogens with other elements gave very different results: carbon tetrachloride showed no flame appearance, although chlorine was liberated. Carbon was deposited, and some sesquichloride formed in crystals, but no salt of platinum or metallic crystals. Phosphorus pentachloride gave a flame the first minute or so, and then evidently enough phosphorus was liberated to alloy with and cause the wire to melt.

In the case of HCl there was an evident decomposition at the temperature and under the conditions. Some PtCl_2 was formed, but we obtained no crystals, nor did we notice any flame appearance around either wire.

In the case of HBr there is just a little doubt that some moisture was in the bulb at the time, so the observations are not recorded here. We are repeating the experiment. It may be remarked that it is a difficult matter to dry HBr without some slight decomposition.

With HF there is very considerable difficulty in carrying out the experiment in a glass vessel. An experiment was made by having the bulb as dry as possible and passing a current of HF through it, but it will only be noticed here that some soluble platinum salt was formed; it will be referred to again when we describe the action on SiF_4 , TiCl_4 , BCl_3 , Al_2Cl_6 , and chlorides of tungsten and molybdenum. . . .

With sulphur, oxides of nitrogen, and SO_2 no apparent action took place. Phosphorus and arsenic vapours destroyed the wire at once. With mercury vapour there was no visible result. With HgCl_2 some platinous chloride was formed and mercury liberated, but no crystals of platinum.

The action on the platinum is evidently far more pronounced when the substances are in what is termed a loose state of combination, as with the halogen compounds amongst themselves.

With substances which do not act upon platinum no visible change takes place on the platinum wire. All the

compounds yet tried containing halogens are decomposed by the hot wire, the liberated halogen acting then upon the cooler portions of the wire, forming a salt which must to some extent be converted into vapour, and, as this comes in contact with the hotter portions of the wire, becomes decomposed into the metal, which is deposited in crystals, and free halogen again. That something of this kind is the case is indicated by the fact that the greater portion of the crystals are formed on the hottest part of the wire; the cold portion has absolutely no metallic crystals on it. The platinous salt formed is deposited for the most part at the top of the globe above the wire: this also indicates that the salt must have been in the state of vapour; at any rate it seems to indicate that platinum salts are in the presence of the halogens to some extent volatile.

The most striking part is the lambent flame that accompanies this decomposition by the heat of the wire.

(About Half real size).

It is more than a mere glow; it moves about similar to a candle-flame, and in some cases—with ICl_3 , for instance—nearly fills the flask. We do not think it can be caused by an oxidation of the halogen, for care was taken to expel all atmospheric oxygen before starting the current. That it is due to the combination of the platinum with the halogen is just possible; but in the case in which the flame appearance is greatest—iodine—there is least platinous salt formed.

As far as we can make out, also, the flame gives a continuous spectrum with dark absorption lines.

In the case of gases and vapours likely to attack cork, a flask, of the shape shown on subjoined diagram, had the neck splayed out and a tube drawn out to fit, the platinum wires being sealed through this.

We are continuing the experiments with some modifications—for instance, putting one of the coils of wire in a powerful magnetic field.

Royal Military Academy, Woolwich,
October 30, 1888.

THE CHEMICAL EXAMINATION OF CERTAIN GUMS AND RESINS.

By ROWLAND WILLIAMS, F.C.S., F.I.C.

CONSIDERING the importance of the subject, the chemical examination of gums and resins has not received the amount of attention which might have been anticipated. One of the most important contributions to our knowledge of the properties of these bodies is the research by Hirschsohn, whose results may be found in *Pharm. Zeit. f. Russland*, p. 225, 1875, and p. 1, 1877; also *Pharmaceutical Journal*, vii., 369, and viii., 389; and "Watts's Dictionary of Chemistry," viii., 1743.

Hirschsohn's work appears to have been mainly devoted to the question of the solubility of certain gums and resins in various volatile liquids, such as petroleum spirit, ether, and alcohol. The information thus obtained has undoubtedly proved useful to other chemists, more especially in connection with the analysis of varnishes.

Mills and Muter (*Journal of the Society of Chemical Industry*, iv., 96) seem to have been the first chemists to undertake a systematic quantitative examination of a number of the most frequently occurring gums and resins. Their results, however, although extremely valuable, would have been even more so if their experiments had included more than one specimen of each kind of resin. Unfortunately, with the exception of xanthorrhæa resin (8 samples) and dragon's blood (11 samples), the bromine absorptions of which were determined, Mills and Muter examined only single samples of varnish resins from a similar point of view.

Mills (*Journal of the Society of Chemical Industry*, v., 221) has also examined the action of potash on certain resins, again using single samples for his experiments. His determinations were made by leaving weighed quantities of the finely powdered resins in stoppered bottles with excess of normal alcoholic potash, allowing to stand for eighteen hours, and titrating back with normal hydrochloric acid.

It seemed possible, therefore, that further research on a larger number of representative specimens of the different varieties of commercial gums might tend to increase our knowledge of this interesting branch of chemistry. With this object in view, a few months ago I commenced an analytical investigation of some of the more important gums. For this purpose I obtained between 40 and 50 samples from several large London firms, to whom I now beg to offer my thanks for their kindness in supplying me with the same. It unfortunately happened that I received only single specimens of some of the resins, but luckily these were, taken as a whole, of the least importance from a commercial point of view. It will be seen that in several instances at least two samples, and in the majority of cases from three to nine samples of the various kinds of resin were submitted to examination, thus allowing a wide margin for every possible difference in constitution between the varieties in question.

In these samples I determined the total potash absorption, the percentage of potash required to neutralise the "free acid," the iodine absorption, ash, and loss on drying at 212° F. The total amount of potash absorbed was found by boiling a weighed quantity of the powdered resin with an excess of semi-normal alcoholic potash for half an hour, adding a few drops of phenolphthalein solution, and titrating back with semi-normal hydrochloric acid. The acidity of the resins was determined by boiling

weighed quantities of the samples with strong alcohol, and titrating with semi-normal caustic potash after addition of phenol-phthalein solution.

The iodine absorptions were ascertained in the well-known manner by means of Hübl's reagent. Ash was estimated by ignition in platinum crucibles, and loss on drying at 212° F. by exposing weighed amounts of the samples to the heat of a boiling water-bath until they ceased to lose weight.

All the estimations were performed in duplicate, and the means of the figures obtained are given in the accompanying table.

A careful examination of these results brings out many interesting features, to a few of which I should like to direct attention.

Animi.—The figures obtained from the three samples examined are, on the whole, fairly concordant—sufficiently so, at any rate, to indicate the ease with which any attempt at sophistication could be detected by an experienced analyst.

Arabic.—These three samples show a considerable difference in many respects, this being most probably due to the gums being of distinct varieties, but unfortunately I was unable to ascertain their exact commercial grades.

Again, the gum senegal differed entirely from the gum arabic.

Copal.—It will be noticed that nine samples of gum copal were examined. These may be conveniently divided into two classes—the Manilla, with saponification equivalents lying between 289 and 318, and the remaining six samples with saponification equivalents varying from 405 to 459. Omitting the last figure (which was obtained from a sample the history of which was unknown), it will be seen that the Sierra Leone, Angola, and Accra varieties have saponification equivalents lying between 405 and 435.

These remarkably constant results, in conjunction with certain other data, prove the impossibility of successfully adulterating gum copal, when this article is submitted to chemical analysis, and at the same time show the readiness with which the analyst can distinguish the different varieties of copal from each other.

Damar.—These three samples show rather wide discrepancies, but even here the saponification equivalents are so extremely high that the application of Koetstorffer's test alone is sufficient to prove the genuineness or otherwise of a specimen of damar.

Elimi.—It will be noticed that this gum has by far the highest saponification equivalent and iodine absorption of any of the samples examined, this, again, rendering any attempt at adulteration difficult, if not indeed impossible.

Kowrie.—The results obtained from the two samples agree moderately well, the slight variance between the respective figures being probably due to the difference in quality of the gums, one being termed "medium," the other "fine."

Mastic.—All the figures obtained in the case of the two specimens of mastic are remarkably close, again rendering futile any attempt at fraudulent admixture with inferior gums.

Rosins.—Perhaps the most notable feature in connection with the rosins is the increase of "free acid" in the refined samples.

Sandarac.—With reference to these samples, the main point of interest is the large amount of "free acid" present, this constituting, in fact, almost the whole of the matter acted upon by caustic potash. This point at once distinguishes sandarac from any other gum which I have examined, and is sufficient to prevent the possibility of fraud.

Shellac.—All the samples gave very similar results, the chief point of interest being that "fine orange" absorbed the smallest percentage of iodine, while "garnet" and "button" had considerably higher iodine absorptions than any of the grades of "orange."

Tragacanth.—The figures obtained were fairly con

* Owing to an accident there was not enough of this sample left for the iodine absorption test.

cordant, the greatest discrepancy being in the percentage of water, the proportion of which is known to vary in different samples to a moderate extent.

The preceding figures will, no doubt, be of considerable service to those who may at any time be called upon to examine the gums and resins of commerce in their ordinary conditions, and also, I trust, to chemists engaged in the

tedious and oftentimes most difficult analyses of varnishes made therefrom.

In conclusion, it gives me great pleasure to express my thanks to two of my pupils—H. Winstanley and C. Boothby—for their able assistance during the progress of this investigation.

THE ESTIMATION OF QUININE BY
KERNER'S METHOD.

By EDELL A. RUDDIMAN.

(Concluded from p. 218).

(5) *On the Amount of Water which should be used in the Application of Kerner's Test to Salts of Quinine other than the Sulphate.*—Dr. Prescott* called my attention to the fact that, in the U.S. Ph., application of Kerner's test to the salts of quinine other than the sulphate, the proportion of ten parts of water to one part of the sulphate formed is not retained. By thus varying the proportion of water, the stringency of the test is subjected to variation. Following, are equations showing the amount of water which should be used if the proportion in the original test of Kerner be preserved. Dr. Lyons has also called my attention to the fact that in the U.S. Ph. test for quinine sulphate itself, the original proportions are departed from, inasmuch as the weighed amount of the crystallised salt is dried before treatment with the water. Therefore the proportions of water calculated below must be multiplied by the factor 0.878 to bring them to the proportions of the U.S. Ph. test for the sulphate. The factor 0.878 is based upon the averages of Henry B. Parsons in 1884, giving 13.84 per cent water as the mean quantity in 1015 samples from 100 ounce cans just opened.

For the Free Alkaloid.

$$756 : 872 :: 1 : x = 1.1534 \quad 1.1534 \times 10 = 11.534$$

$$756 : 126 :: 1 : x = 0.166 \quad (\text{after evaporation on water-bath, and then adding water, } 7H_2O \text{ taken up}).$$

$$11.534 + 0.166 = 11.700 \quad 11.7 \text{ c.c. of water to be added to 1 grm. of the alkaloid.}$$

Hydrobromide.

$$845.6 : 872 :: 1 : x = 1.0312 \quad 1.0312 \times 10 = 10.312$$

$$845.6 : 90 :: 1 : x = 0.106 \quad (\text{correction for water of crystallisation}).$$

$$10.312 - 0.106 = 10.206 \quad \text{c.c. of water to be added to 1 grm. of hydrobromide.}$$

$$15.309 \quad \text{c.c. of water to be added to 1½ grm. of hydrobromide.}$$

Hydrochloride.†

$$788.8 : 872 :: 1 : x = 1.1054 \quad 1.1054 \times 10 = 11.054$$

$$788.8 : 126 :: 1 : x = 0.159 \quad (\text{water of crystallisation}).$$

$$11.054 - 0.159 = 10.895 \quad \text{c.c. of water to be added to 1 grm. of hydrochloride.}$$

$$16.342 \quad \text{c.c. of water to be added to 1½ grm. of hydrochloride.}$$

Bisulphate.

$$1096 : 872 :: 1 : x = 0.7956 \quad 0.7956 \times 10 = 7.956$$

$$(NH_4)_2SO_4 + 16H_2O.$$

$$1096 : 126 :: 1 : x = 0.114 \quad (\text{water of crystallisation}).$$

$$7.956 + 0.114 = 8.07 \quad \text{c.c. of water to be added to 1 grm. of bisulphate.}$$

The U.S. Ph. test of the free alkaloid is more stringent than for the sulphate, since it directs that for every 10 c.c. of water there shall be sufficient alkaloid used to make 11.534 grm. of the sulphate. In case of the hydrochloride or the hydrobromide, the test is considerably more severe, first, because an insufficient amount of water is used, and second, because in the conversion of the hydrochloride or hydrobromide into the sulphate, direction is made to use hot water. In testing the bisulphate the official method directs that, to the mixture of the salt and water ammonia be added to neutralisation, and then sufficient water added to make the mixture measure 10 c.c. This is to be criticised for two reasons: first, because it does not take into account the fact that 1 grm. of the bisulphate forms only 0.7956 grm. of the normal sulphate, and second, because there is no allowance made for the space occupied by the salt, and the proportion of water added to the sulphate formed varies inversely with the volume of the salt. To 1 grm. of the bisulphate of quinine as tested in the U.S. Ph. there should be added in all (taking into consideration the water of ammonia) 8.07 c.c. of water.

In applying the U.S. Ph. tests to the salts of quinine other than the sulphate, some difficulty* has been experienced in obtaining the required 5 c.c. filtrate. Various methods have been offered to obviate the difficulty, but the one proposed by C. N. Lake† seems to be the one which the most nearly corresponds to the original test. It is to increase both the amount of salt and of water yet preserving the proportion between them. Working with the free alkaloid I found in using the ratio of water to the alkaloid as directed in the official test, by taking 1½ times as much as there stated, the required 5 c.c. filtrate could be obtained with a little difficulty, but doubling the amount no difficulty was experienced. By taking 1½ grms. of the alkaloid and 17.5 c.c. of water, which is in the proportion of 10 parts of water to 1 part of the sulphate formed, the 5 c.c. of filtrate can be easily obtained. With the hydrochloride and hydrobromide I had no difficulty by taking the amount of the salt and water as directed in the pharmacopœia. Since the amount of water which should be used is greater than the amount which is used, there was of course no difficulty when the correct amount was taken. In case of the bisulphate the required amount of filtrate may be obtained either by doubling the amounts directed in the pharmacopœia or by taking 2½ grms. of the salt and the theoretical amount of water, which is 20.09 c.c.

Conclusions.—(1) The pharmacopœial test of commercial quinine sulphate when applied as there directed does not, as a rule, correctly indicate the amount of cinchonidine sulphate present. By using a higher temperature and water sufficient to dissolve all of the salt, a closer approximation to the real amount of cinchonidine contained therein may be obtained.

(2) The temperature of the resulting liquid at the time the titration is completed has a considerable effect upon the amount of ammonia water necessary to re-dissolve the precipitate. For every degree that the temperature of the titration is above 15°, there should be added 0.148

* 1887; *Organic Analysis*.

† The authority for giving the hydrobromide of quinine as having but one molecule of water of crystallisation is found in the "French Codex, p. 148, and in "Ladenburg's Handwörterbuch, i., 250.

‡ On Kerner's volumetric method as applied to the hydrochloride. *Archiv. der Pharm.* [3], xix., 1. *Jahresb. der Pharm.*, 1881—2, p. 662.* 1885; *Contrib. Dep. Pharm. Univ. Wisc.*, 1885, ii., 17. *Proc. Am. Pharm. Assoc.*, 1886, xxxiv., 601.† 1885; *Drug. Circular.*, xxix., 199.

c.c. to the number of c.c. of ammonia water of sp. gr. 0.920 used.

(3) In my experiments I found that 0.36 c.c. of water of ammonia, sp. gr. 0.920, is necessary to precipitate and re-dissolve 1 m.grm. of cinchonidine sulphate, *i.e.*, in the quantitative estimation of cinchonidine sulphate in quinine sulphate, every 0.36 c.c. of ammonia used in titrating the 10 c.c. of filtrate from the sample being tested over that used in titrating the 10 c.c. of filtrate from the standard quinine, indicates 1 m.grm. of cinchonidine sulphate in 1 grm. of the sulphate of quinine tested, or 0.1 per cent.

(4) In estimating the cinchonidine sulphate in commercial quinine sulphate to get a result nearest correct, it is necessary to dissolve the salt. This can be done by using a temperature of 100° C. and 30 parts of water; if more water be used the temperature need not be so high, but while the amount of impurities remains about as found at present, 30 parts of water will be sufficient.

(5) The proportion of water to the sulphate in the official test of the forms of quinine is not precisely the same as in Kerner's original test. If the proportion in the latter case be retained, there should be used for 1 part of the free alkaloid 11.7 parts of water; for the bisulphate, 8.07 parts of water; for the hydrochloride, 10.895 parts of water; and for the hydrobromide, 10.2 parts of water. Also for the dried sulphate 10.144 parts of water.—*Journal of Analytical Chemistry.*

AN INQUIRY INTO THE RELATIVE VALUE OF ALUMINIUM AND ITS ALLOYS TO THE ARTS.*

By H. PEMBERTON, Jun.

OF late years a considerable amount of attention has been paid to the metal aluminium. Much has been written about it; many plans have been proposed for its extraction, and numberless patents, embodying these plans, taken out, both in the United States and abroad. In fact, the subject appears to possess a species of fascination, as it has attracted attention from all directions. Parties supplying the raw materials or chemicals used in the experiments report that the demand for such comes not only from chemists and metallurgists, but also from business men, lawyers, and professional men of all kinds. The long list of foreign patents on the subject shows how widely it attracts interest. Prof. Richards's treatise on aluminium contains fifty-four pages—one-sixth of the entire book—on the manufacture of the metal by processes other than the regular one of Deville.

There is no difficulty in giving an explanation of this. Of all the metals, properly so called, the compounds of which make up the crust of the earth, aluminium is the most abundant. This statement is literally true; there is no exception to it. It is evident, therefore, that there can be no difficulty in obtaining material to work upon. Now, taking ordinary clay as an instance, it can be readily shown that in every cubic yard there is at least 800 pounds of aluminium, the lowest recorded price of which is five dollars a pound. Clay can be had, in many cases, at a cost not exceeding that of digging it out. The apparent profit can readily be calculated.

The practical outcome, however, of all this work, and of all these experiments, is that the only process by which any quantity worth speaking about of the pure metal aluminium—in contradistinction to its alloys—has ever been extracted, is the process of Deville, established about a third of a century ago. Modifications in the preparation of the materials have, indeed, been made. But the main features of the process, and the sequence of opera-

tions, have remained unchanged. The large aluminium works now just about starting, near Birmingham, England, employ the same chemicals, and rely upon the same reactions that the French chemist did in the fifties.

This company—the Aluminium Company, Limited—has gone into the manufacture on a scale never heretofore approached. According to the descriptions in a number of English technical journals, the works comprise a plant of twenty furnaces for the manufacture of metallic sodium by the Castner process, with a total capacity of about 1500 pounds a day; a set of twelve regenerative heating furnaces, containing sixty retorts for the manufacture of the double chloride of aluminium and sodium, turning out about 5000 pounds every twenty-four hours; a Weldon chlorine plant; and furnaces for reducing the aluminium from the double chloride by means of the sodium. The total capacity of the works is about 500 pounds of aluminium daily. According to the *CHEMICAL NEWS*, (vol. lviii., p. 65) the production of the entire world has heretofore not been over fifty pounds a day. It appears, therefore, that the new company can manufacture in five or six weeks as much as has hitherto been produced in a year. The selling price of the aluminium has been placed at about five dollars a pound as against eleven dollars, lately. The reduction is due partly to the large scale of manufacture, but principally to the cheapening of the cost of the sodium by Mr. Castner's process. It is to be noted that the aluminium made by this company will be in the form of the pure metal unalloyed. If it is desired to produce alloys, they can only be made, or, at any rate, they have only been made, by first manufacturing the metal and then alloying it.

Exactly opposite is the case with the Cowles electric smelting process. Here the aluminium has always been produced as an alloy, with either copper or iron. The manufacture of the pure metal on a commercial scale does not appear to have been successful so far, and it is probable that the large demand for the alloys has prevented proper attention being given to this branch of the subject. There is no inherent reason why the metal itself should not be produced, but as a matter of fact, up to this date, such has not been the case.

There is one point connected with this process which is worth drawing attention to; that of the reduction of aluminium from its oxide in the presence of carbon, at a high heat. The discovery of this property of the element was as radical and as unexpected as the discovery of a new oxide would have been. All previous efforts to accomplish this had been utterly fruitless, so much so that the hope of so doing had been almost entirely abandoned. Only a few years before the Messrs. Cowles took out their patents, the late Mr. Walter Weldon asserted that it would be about as sensible to try to get five from two times two as to reduce alumina by carbon. "Never prophesy unless you know," said Artemus Ward. This property of the metal is worth drawing attention to, as the practical results of the new process appear to have overshadowed a discovery very interesting from a scientific point of view.

The electro-smelting process appears to have been making great advances of late. A description of it was embodied in a "Report of the Committee of Science and the Arts of the Franklin Institute" (*Journal of the Franklin Institute*, July, 1886). Since this report was published several improvements have been made. It has been found practicable to tap the furnace, and allow the molten metal to flow directly into the ladle or into slabs, instead of letting it cool in the furnace and then putting it cold into crucibles to be re-melted. This has practically doubled the capacity of the plant. Another improvement has been in the use of bauxite, as well as corundum, for a raw material, thus ensuring an abundant supply of alumina. The works at Lockport, N.Y., have now two dynamos of 217 electric horse-power each, driven by water-power. The new establishment at Milton, England, has a 402 E. H. P. machine, put up experimentally and

* Read before the Franklin Institute, September 19, 1888.

to be followed by others. Both of these works are reported to be running day and night.

It appears, then, that the aluminium industry has at length attained a firm footing and is well established. The two lines of manufacture differ essentially in their characteristics. One is a chemical process, the other a metallurgical. One produces the pure metal only, the other only its alloys. One is a complicated process, the other a simple one. Indeed, the Cowles process is extremely simple, consisting, as it does, of only the dynamo, with the power to drive it, and the application of its current to the mixture of carbon, alumina, and the metal to be alloyed. Compared with this, the Deville process is a very elaborate one. Compared with any process, it is a very elaborate one. Indeed, it is doubtful if in the whole field of chemistry and metallurgy together there can be found any process which involves such an intricate series of operations as this one does. There is a department for preparing the alumina, a department for preparing the iron and carbon compound (Castner's patent), another for manufacturing the metallic sodium, another for re-working two-thirds of the sodium remaining as carbonate from imperfect reduction. (This, indeed, is done in an adjacent works, but has to be paid for, of course, just the same). There is a department for manufacturing chlorine by the Weldon process; another for mixing the alumina, carbon, and salt, moulding and drying the same; another for treating this mixture with chlorine at a red heat for the production of the double chloride of aluminium and sodium, and finally, one for treating the double chloride with sodium by which the alumina is reduced to metal. The manufacture of some high-priced organic compound—for instance, Fahlberg's saccharin—may approach this, but it is doubtful if it exceeds it. The Solvay process of manufacturing soda-ash has often been cited as one having had a long up-hill fight. But the Solvay process had the additional struggle of having to manufacture its product for less than two cents a pound, or else not at all, whereas metallic aluminium is sold for twice as many dollars a pound. It needs no expert to see that the cost of the aluminium in alloys, as made by the electro-smelting process, must necessarily be only a fraction of that of the metal made by the Deville. It follows, therefore, that the latter process will not be likely ever to compete with the former in the manufacture of alloys, but will have as its legitimate field the production of the pure metal. It is dangerous to assert a negative. But it is hard to see how there can be any escape from the above deduction. Perhaps a possible exception may be named in the case of certain alloys of aluminium and silver—such as *tiers argent* and a few others of like kind, used in table-ware.

There are three properties, or characteristics of aluminium that make it valuable in the arts. It is a light metal (sp. gr. 2.56), being about one-third as heavy as iron. It is a pretty metal, and not very readily acted upon by atmospheric influences. In this respect it rivals silver, which is blackened by sulphuretted hydrogen, by which aluminium is not affected. Upon exposure for some time, however, or by handling, the surface loses its brilliancy and becomes, through oxidation, more or less "dead," resembling tin or zinc, though superior to them, as the colour is much whiter. In the third place, it is a fairly strong metal, about equal to brass. It is destined to play a valuable rôle in the manufacture of philosophical instruments. Prominent manufacturers state that the weight of theodolites, levels, compasses, sextants, &c., is about one-third less when made of it, and seem to think that there is no doubt of its being largely employed at the quoted English price. All the bearings and wearing surfaces of these instruments must still be made of brass, as aluminium is not hard enough. It is coming into use for making beams of chemical balances with a capacity up to as much as 200 grms., and has long been used for the smaller weights. The moulds for casting such beams are the same as have been used for the ordinary bronze. Opera and field-glasses, when made of it, are much lighter

and can be used with great ease and comfort. It cannot be employed for cooking utensils, as it dissolves easily in organic acids in the presence of chlorides, such as common salt (Roscoe). A few other uses in which the pure metal appears to advantage are aluminium leaf, fine wire lace, certain surgical instruments, suture wire, dental plates, &c. Aluminium jewellery has failed to make any headway; it tarnishes too easily and becomes brittle.

It will be observed that nearly all of the above uses are for objects small in size. Many suggestions have been made for its use on the larger scale, as in aerial navigation, or for engineering and constructive purposes. Some of these are of a very sensational nature, as for example:—

"The dead weight of trains could be saved by constructing freight and passenger cars of aluminium. . . . Ships larger than the *Great Eastern*, with less draught, could be constructed nearly entirely of aluminium, including the machinery and boilers which at present weigh down vessels seriously. . . . Railway beds, sleepers, ties, rails, bridges, and all, will be cast solidly in their places, with airy aluminium palace cars dancing over them 100 miles an hour or more," &c.

There is a fallacy involved in all such writing which may be worth showing up. The writer's attention is pre-eminently attracted by the low specific gravity of the metal. When employed in any construction where it will be required to withstand severe stress, the metal with which it will immediately come into rivalry will be steel. The specific gravity of steel is almost exactly three times that of aluminium. Of course an inch rod of the latter metal will therefore weigh only one-third as much as an inch rod of steel. But when we examine the tensile strength of the two we find that steel has three times the strength of aluminium. It follows, therefore, that to make the aluminium rod of the same strength as the steel, it must be three times the size. The two rods will now weigh exactly the same. Where, then, is the advantage of the low specific gravity of the aluminium?

The extraordinary qualities of many of the aluminium alloys have long been known. The bronze is the strongest of cast metals, and, when rolled, the strongest of rolled metals. Nor does it corrode as ordinary bronze does, and its fine golden colour gives it a very pleasing appearance. Aluminium brass is noted for its great strength, for its extraordinarily high elastic limit, and for its cheapness. Being composed of equal weights of zinc, copper, and 10 per cent aluminium bronze, it contains only $3\frac{1}{2}$ per cent of aluminium; hence its lower price.

Aluminium iron is now extensively used in the production of wrought-iron castings (Mitis castings). That the fusing-point of wrought iron should be reduced almost 500° by the addition of only 1-1000th of its weight of aluminium, is another instance of the wonderful properties of this extraordinary metal. The effect of its addition to cast iron is shown in a paper on this subject by W. J. Keep (*Journal of the Franklin Institute*, cxxvi., p. 220). Large quantities are now being used also with steel, a very minute amount ensuring the solidity of the castings. Indeed it appears that aluminium will be used almost universally in the metallurgy of steel and of iron, including puddled iron. Its strength-giving properties are extraordinary. There is hardly any metal with which it will not alloy; and it alloys with nothing that it does not improve. It would be only tedious to attempt to describe its endless applications. Two of the most important, however, may be noticed. The bronze is destined to play an important part in the manufacture of cannons. The war that is waging between experts, regarding the relative value of cast and of built-up guns, is so fierce that it appears difficult to obtain a discussion on the subject that does not involve the introduction of this pet fight. Aluminium bronze can, of course, be used for either type, although the cast gun is naturally much the cheaper. Such cannon could be made to possess

* See *Engineering*, London, April to June, 1888.

very easy. The bromide is decomposed at the ordinary temperature here of about 30°C ., as is shown by the liberation of iodine by passing carbon dioxide through the mixture; so that it may be possible to obtain all the bromine if the current of gas is continued sufficiently long.

And the iodine of an iodide may be distilled from mixtures with chlorides and bromides by ferric chloride, chromic acid, and hydrogen dioxide.

Thus in a fair way is realised the solution to the question of directly determining bromine, chlorine, and iodine quantitatively in a mixture of the haloid salts by methods purely volumetrical.

Rangoon College, October 11, 1888.

THE AUSTRALASIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

CHEMICAL SECTION.

As we have already intimated the New South Wales papers, in the exercise of their indiscretion, have allotted but a very scanty space to the proceedings in this Section.

Thus of the Presidential Address delivered by Prof. BLACK, D.Sc., we find it merely reported that the speaker discussed chemistry in reference to education. He argued that chemical training should be given in all schools, especially in those of higher grade. In this respect there was room for a great improvement.

Mr. C. A. SMITH, F.I.C., F.C.S., read a paper on "Butterine" as an article of food. He explained that this article, which he should preferably have named Margarine, was first made in Holland, about 1869, by one Nierge, and that at first it was sold as butter. He recommends its use as a fuel-food, it being made of carefully prepared dripping, churned up with milk, and coloured to imitate butter. He then described the margarine factory at Waterloo (probably near Melbourne), where the output is about 3 tons weekly, most of which is exported to Java, Mauritius, and the Cape.

Mr. W. A. DIXON gave a paper on the "Formation of Coal." The examination of some coal from New Zealand and the other colonies had led him to the conclusion that the chief differences in coal were due to the original nature of the vegetable matter of which they were composed. The best ligno-cellulose was originally composed of resins, and Cannel coal appeared to be derived from adipo-cellulose mixed with ligno-cellulose.

The Secretary, Mr. HAMLETT, read a paper, by Mr. F. Ratte, on "Means of Popularising the Study of Crystallography,"—certainly a difficult undertaking.

Mr. J. H. MINGAYE, F.C.S. (Analyst and Assayer to the Department of Mines), read a paper on the "Discovery of Tellurium in certain Bismuth Ores, found near Captains' Flat, in New South Wales." The physical characteristics of the minerals had been described by T. W. E. David, B.A., F.G.S., Geological Surveyor to the Department of Mines.

Mr. POND announced the fact that he had found tellurium in 1885 in New Zealand in some silver ores to which his attention had been called by Sir James Hector.

Mr. HAMLETT read a paper sent in by Mr. Edgar Hall, F.C.S., of the Sunny Corner Silver Mine, on "Silver Smelting, Rich Silver Mattes, and their Treatment, and on Kernel Roasting." He showed that the main object of the smelter was to get clean slags. He did not consider that the dissemination of matte globules satisfactorily explained the losses of silver, as he had detached perfectly pure crystals from the very heart of the pot from slags of every kind, which yet often contained more silver than the main body of the slags. He thought that "high" silver slags might be due to the property possessed by silver of passing from already solidified portions of a body in which it is present into any portions which still

remain liquid. The difficulties found in smelting certain classes of silver ores were next described, and remedial measures were proposed. The paper closed with an account of the process known as "kernel roasting."

In the discussion which followed Mr. POND observed that if the Section had done nothing more than produce this one paper it had done valuable work.

Professor LIVERSIDGE furnished Notes on the projected Chemical Laboratory for the University of Sydney, with plans and diagrams of the apparatus to be erected. The new buildings will be 150 feet by 84 feet, and will include a main laboratory 72 by 36 feet, affording room for 130 students engaged in practical work. We shall be happy to learn that the facilities thus to be created are fully utilised.

Two important papers read are not reported: one by Mr. W. Skey on "Gold—its Formation in our Reefs, with Notes of Some of its Newly-discovered Reactions." Mr. DON also read a paper on the question "How Gold came into the Reefs."

Two further papers, namely, by Mr. J. H. Maiden on the "Chemistry of Indigenous Australian Products," and by Mr. W. M. Hamlett on the "Action of the Nepean Water on Tubes and Boiler Plates," were taken as read.

We the more regret the insufficient manner in which the proceedings of the Chemical Section are reported, because it does not appear certain whether and when the Transactions of the Sydney Meeting will be published in full. At least the question of ways and means seems by no means fully decided.

OBITUARY.

PROFESSOR TUSON.

WE regret to announce the death, at the premature age of fifty-six, of Prof. Richard Vine Tuson, who for the last twenty-eight years has held the post of Professor of Chemistry in the Royal Veterinary College, London.

Prof. Tuson began his scientific training under Prof. Graham, at University College, and was afterwards Assistant successively to Prof. Ronalds, in Galway, and Dr. Stenhouse, at St. Bartholomew's Hospital, in London. He was afterwards elected Lecturer on Chemistry to the Medical School of Charing Cross Hospital, where he was universally popular with students and teachers. A few years later he tried for and obtained the Professorship which he held until his death, which took place, in his house at Erith, on the 31st of October, 1888.

Prof. Tuson was a thorough chemist and an able teacher and experimenter. Various scientific papers stand in his name, but his most important literary labour was the new edition of Cooley's well-known "Dictionary of Receipts," which he prepared with care and skill. He was a good and most amiable man, and his untimely death, from heart disease,—which it appears had been making unsuspected progress in his system for years,—will be lamented by a wide circle of friends.

NOTICES OF BOOKS.

Chemical Notes and Equations, for the Use of Students.

By R. MILNE MURRAY, M.B., F.R.C.P.E. Third Edition. Edinburgh: McLachlan and Stewart. London: Baillière, Tindall, and Cox.

THE author of this work says, in a note prefixed to his first edition (1879), that his "Notes" are not intended to take the place of a systematic text-book or of lecture-notes; they are to afford to the junior student a means of ready reference. To that unfortunate and ubiquitous

personage "the student preparing for examinations" they are recommended as a means for "refreshing his memory on the chief facts of inorganic chemistry."

In a note to the present edition mention is made of two revisions. Nevertheless a third such operation would not be entirely out of place. Thus on p. 2 we find a mixture described as "a substance formed of two or more parts which are separable by mechanical means." As an example is given the atmosphere, a mixture of oxygen and nitrogen. But when we require to separate these two gases we are obliged, as the author must be perfectly aware, to employ the purely chemical means of causing the oxygen to enter into a non-gaseous combination.

We can scarcely admit the author's view that "abase is always an oxide," since a few pages further on he speaks of the well-known sulphur bases.

In the table of atomic weights that of platinum is still given as 197.5, instead of the more correct value 194.8.

On p. 56 the student is told that fluorine has not been got in the free state, a statement which is decidedly out of date.

Red phosphorus, it is said, is "not combustible,"—an evident exaggeration.

The above-mentioned points, and a few others which the reader will not fail to discover, stand in need of rectification.

Les Théories et les Notations de la Chimie Moderne (The Theories and Notations of Modern Chemistry). By ANTOINE DE SAPORTA, with an Introduction by C. FRIEDEL. Paris: J. B. Baillière et Fils.

This book belongs to a series entitled "Bibliothèque Scientifique Contemporaine," which is by no means exclusively confined to scientific subjects.

M. de Saporta, in the volume before us, undertakes to lead his countrymen to the same point of view in chemical science which has been definitely adopted in every civilised country save France alone. M. Friedel, in his excellent Introduction, admits that "by a singularity which is not unexampled in the history of French science and industrial art,—we may instance the reception accorded beyond the Channel to the doctrine of organic evolution,—a theory the first foundations of which are of national origin finds the greatest difficulty in taking root among us."

How little M. de Saporta is swayed by French convention appears from the fact that, as a symbol for nitrogen, he recommends N in preference to Az.

Again, he recognises that the term "metalloids," so frequently used by his countrymen for the non-metallic elements, is "perfectly improper." It leads to the belief that all substances not strictly metallic are by their characters true quasi-metals. He announces that the barrier erected by Science between the metals and the non-metals is purely arbitrary and fictitious, whilst the latter class differ quite as widely among themselves as they do from the true metals.

When speaking of the theories of Newlands, Mendeleeff, and Meyer, M. de Saporta makes two remarks worth notice. He complains that the claims of priority, as between the three chemists just named, are difficult to decide. We have been of opinion that all disputes on this subject had come to an end with the publication of the original papers of Mr. Newlands. Secondly, our author calls attention to the fact that no French name has the right to figure along with those of the three authors just mentioned. But with this he does not consider that his countrymen can be justly reproached, since they excel rather in directing their experiments with clearness, and interpreting them correctly, than in hovering, like the Germans, amidst theories very elevated but often very cloudy.

He remarks that Mendeleeff and L. Meyer return, in some sort, to the theory of chemical philosophy as laid down by Lavoisier and his immediate successors. He contends that the anomalies will disappear from the

periodic tables, if, instead of fixing our attention on the free elements, their hydrides, or their chlorides, we consider the corresponding oxygen compounds.

The hypothesis of Prout is merely considered in a note.

Into the great questions of the origin and the nature of the received elements, and the prospect of their ultimate decomposition, the author does not enter.

The work may be regarded as a good compendium of the principles of chemistry valuable for readers acquainted with elementary details. The chief shortcoming which strikes us is the meagreness of the table of contents and the index.

CORRESPONDENCE.

ANCIENT MORTARS.

To the Editor of the Chemical News.

SIR,—*A propos* of Mr. Spiller's paper on the "Analysis of the Ancient Mortar from the Roman Wall of London" (CHEMICAL NEWS, vol. lviii., p. 189), and Mr. Irving's letter on the subject (vol. lviii., p. 219), perhaps I may be allowed to point out that about two years ago Messrs. Crookes, Odling, and Tidy presented a most important "Report on the Action of Water on Lead" to the Water Committee of the Huddersfield Corporation, in which it was stated that soft waters which had a solvent action upon lead could be rendered lead-proof by introduction of a certain proportion of silica. The silication was recommended to be carried out by means of a mixture of flint and limestone, but, as nearly as I can remember, no special reason was given for the use of these materials.

Messrs. Carnelley and Frew, in a paper on "The Corrosion of Leaden Water-pipes" (*Journ. Soc. Chemical Industry*, vol. vii., p. 15), call attention to the fact that while either sand or calcium carbonate added separately to distilled water exerts a protective action, a mixture of the two is even more effective. This result they explain by assuming the formation of calcium silicate, as they found that ground Wollastonite and old mortar acted in the same manner.

In the course of a recent investigation on this subject I had occasion to make a number of experiments very similar to those recorded in Messrs. Carnelley and Frew's interesting paper, and my results quite confirm their statements.

The rapid corrosive action of distilled water on lead in presence of air is, of course, well known. I found that sand or calcium carbonate, when added separately, prevented this action to a considerable extent, while a mixture of the two rendered distilled water practically lead-proof.

I think it probable, therefore, as Messrs. Carnelley and Frew have suggested, that the addition of sand to calcium carbonate, in presence of water, results in the formation of calcium silicate, and this comparatively quickly.—I am, &c.,

ROWLAND WILLIAMS.

28, Pall Mall, Manchester,
November 5, 1888.

The Formation of Amido-butyric Acid by the Direct Fixation of Ammonia upon Crotonic Acid.—M. Engel.—Crotonic acid fixes the elements of ammonia at 100°, and with great ease. The yield is almost theoretic, nothing being formed as a secondary product save a little oxybutyric acid. The product obtained is very probably β -amido-butyric acid.—*Bull. de la Soc. Chim. de Paris*, Vol. I., No. 2, 1888.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 15, October 8, 1888.

This number contains no chemical matter.

No. 16, October 15, 1888.

Certain Double Yttrium and Potassium or Sodium Phosphates.—A. Duboin.—The author has obtained the above phosphates by causing amorphous yttrium phosphate to react in the dry way upon potassium sulphate, or by causing pure yttria to react at a high temperature upon potassium or sodium metaphosphates and pyrophosphates.

Study of the Combustion-heat of Dextro- and Lævo-camphoric Acids, and of Camphora-racemic Acid.—W. Louguinine.—The author's object was to determine the influence of physical isomerism upon the heats of combustion. He found that no difference existed in this respect.

The Alkaloids of Cod-liver Oil.—Arm. Gautier and L. Morgues (continuation).—In this memoir the authors describe the fixed bases, aselline and morrhaine.

On Propylphycite.—Ad. Fauconnier.—The "propylphycite" described by Carius in 1865 is merely glycerin.

On the Latent Colours of Bodies.—G. Govi.—If we agree to consider as the peculiar colour of a body that which results from the radiations diffused or transmitted by such body in the greatest quantity, we may say that such peculiar colours are still very imperfectly known. The causes of this imperfect knowledge are as follows:—The light of the sun or diffused daylight not containing all the visible coloured radiations cannot always show us the true colours of bodies. Even the light given by incandescent solids which contain all the visible radiations, do not suffice to show us bodies in their true colour. To discover this true colour it is necessary to illuminate the bodies by a continuous complete spectrum containing neither rays nor absorption bands, or by simple radiations obtained from incandescent gases. These may be, and there really are, bodies whose peculiar colour is invisible or latent in the ordinary conditions of illumination.

No. 17, October 22, 1888.

Combination of Benzoic Aldehyd with the Polyatomic Alcohols.—H. Maquenne.—In the acetals derived from a polyvalent alcohol, each mol. of aldehyd necessarily saturates two alcoholic functions. If the number of these is odd the aldehyd will always leave at least one free, whence it results that the elementary composition of these acetals is so different when we pass from any polyatomic alcohol to its nearest homologue that analysis can distinguish them at once. Here, therefore, is a new means of determining if an alcohol as an even or odd atomicity.

Action of Hypophosphorous Acid upon Benzoic Aldehyd: Formation of a Dioxyposphinic Acid.—J. Ville.—The facts observed by the author show that hypophosphorous acid unites with benzoic aldehyd to form a triatomic monobasic acid, the dioxyposphinic or dioxybenzylene-phosphinic acid.

Action of Sodium Hypobromite upon Certain Nitrogenous Aromatic Derivatives, and Reaction Distinguishing the Hippuric and Benzoic Derivatives.—G. Denigés.—If we boil for a few moments a little sodium hypobromite containing an excess of alkali with a small quantity of hippuric acid or of a hippurite, a few bubbles of gas escape, and there is formed a reddish

yellow turbidity which increases. The precipitate deposited is a bromine derivative, resembling a vermillion red powder. Benzoic acid, under the same conditions, gives nothing similar. Glycol decolourises the hypobromite with an escape of nitrogen gas. The author has examined the action of sodium hypobromite with a number of compounds of the aromatic series, and has obtained the following results:—*Benzamide* and *Benzonitrile*.—Nothing in the cold, but a red precipitate on boiling. *Aniline*.—The aqueous solution, even if very dilute, gives an orange precipitate. *Methylaniline* and *Dimethylaniline*.—A yellow precipitate, rather greenish in the cold, but turning more to a red shade on boiling. *Toluidine*.—The same results as aniline, the precipitate rather more brown. *Anilides*.—Nothing in the cold; on boiling, a reddish precipitate. An odour of methyl cyanide is given off. *Metaphenylene-diamine Hydrochlorate*, *Diamido-benzoic Acid*; *Toluylene-diamine*.—A maroon-red precipitate both in cold and heat. *Ferrocyanides*, *Ferricyanides*, *Nitroprussides*.—On boiling, a red precipitate of ferric hydrate. *Pyridin*.—Nothing. *Quinolein*.—An orange-red precipitate only if aniline is present.

Bulletin de la Société Chimique de Paris.
Vol. I., No. 2, July 20, 1888.

Action of Hydrochloric Acid upon Cupric Chloride: Hydrochlorate of Cupric Chloride.—M. Engel.—The author's results agree closely with those of M. Paul Sabatier (*CHEMICAL NEWS*, vol. lviii., p. 220).

Action of Hydrochloric Acid upon the Solubility of Stannous Chlorides: Hydrochlorate of Stannous Chloride.—M. Engel.—It results from the author's experiments that a definite hydrochlorate of stannous chloride may be obtained. It is crystalline, and melts about -27° .

Action of Hydrochloric Acid upon the Solubility of Cobalt Chloride: Hydrochlorate of Cobalt Chloride.—M. Engel.—This paper does not admit of useful abstraction.

On Neutral Platinum Chloride.—M. Engel.—There exists a neutral platinum chloride having the composition $\text{PtCl}_4 + 4\text{H}_2\text{O}$, and a hydrochlorate of the chloride $\text{PtCl}_4 + 2\text{HCl} + 6\text{H}_2\text{O}$. The latter compound is the more soluble.

Analysis of a Mixture of Silver Chloride, Cyanide, Sulpho-cyanide, Ferricyanide, and Ferrocyanide.—Jules Teissier.—This question, which occurs in the analysis of mixtures serving for purifying coal-gas may be solved as follows:—We operate upon a saturated mixture of compounds derived from gas. After having exhausted with distilled water and eliminated the tarry matters by repeated boilings and filtrations, all the insoluble bases are precipitated by means of sodium carbonate, and all the acids capable of forming insoluble barium salts by means of barium nitrate. The last filtered liquid is precipitated with silver nitrate. The operations, including washing on the filter and the desiccation of the precipitate, are performed in the dark, and require eight days. The mixed precipitate is weighed and found 1825.7 m.grms. The equivalents of the five compounds being respectively 143.5, 134, 166, 536, and 322, if we denote by x, y, z, u , and v , the number of the equivalents of these compounds entering into the mixed precipitate, we have—

$$143.5x + 134y + 166z + 536u + 322v = 1825.7 \text{ m.grms.}$$

Carbonate of soda is heated in a large platinum crucible until completely dry; the mixed precipitate is then added, and then potassium nitrate. The crucible is closed and heated, first over a very small spirit lamp, and the heat is gradually increased by changing the lamp, a Bunsen burner being used at the conclusion. The total ignition lasts an hour. In this manner the sulphur of the sulpho-

cyanide passes into the state of potassium and sodium sulphate; the chlorine of the silver chloride passes also to the potassium and sodium. The contents of the crucible are exhausted with distilled water, metallic silver and ferric oxide being left undissolved. In the solution thus obtained the sulphur is determined as barium sulphate, and then the chlorine as silver chloride. For the former we find 227.17 m.grms., whence the weight of the silver sulphocyanide = 1618.5 m.grms. This is the value of 1662 in the above equation. The silver chloride weighs 33 m.grms., the value of 143.5x. The equation is thus reduced to $134y + 536u + 322v = 174.2$. We have still three unknown quantities, to find which we dissolve in nitric acid the residue left at the bottom of the crucible. We determine the silver as chloride and the iron as ferric oxide. We find 1475.2 m.grms. of silver and less than 2 m.grms. of iron. Hence it may be regarded as an impurity, wherefore neither ferrocyanide nor ferricyanide are present and u and v are nul. $134y = 174.2y = 1.3$. The 1475.2 of silver chloride represent 1110.2 of metallic silver. Thus we have:—Silver chloride, 33.0 m.grm.; silver cyanide, 174.2 m.grm.; silver sulphocyanide, 1618.5 m.grm.

Chemical Study of the Essence of Eucalyptus Globulus.—R. Voiry.

Chemical Study of the Essence of Cajeput.—R. Voiry.—These papers have little general interest.

MISCELLANEOUS.

Society of Arts.—The One Hundred and Thirty-fifth Session will commence on Wednesday, the 21st November, with an Opening Address by the Duke of Abercorn, C.B., Chairman of the Council. Previous to Christmas there will be four Ordinary meetings, in addition to the Opening Meeting. At the first ordinary meeting of the Society a paper will be read by Colonel Gouraud, on "The Phonograph." This will be followed by one by Mr. Henry Edmunds, on "The Graphophone." At the other two meetings to be held before Christmas the papers will be by Mr. W. H. Deering on "Explosives," and by Mr. W. J. Dibdin, on "Standards of Light." Among the papers announced for the latter part of the Session may be mentioned—"Manufacture of Sèvres Porcelain," by Mr. E. Garnier (Director of the Sèvres Manufactory); "The Forth Bridge," by Mr. Benjamin Baker; "The Channel Tunnel," by Colonel Hozier; and "Secondary Batteries," by Mr. W. H. Preece, F.R.S. The first course of Cantor lectures will be by Captain W. de W. Abney, C.B., F.R.S., on "Light and Colour;" the other lecturers will be Mr. Alan S. Cole, Mr. W. J. Linton, Mr. Walter Crane, Mr. C. V. Boys, F.R.S., and Mr. H. Graham Harris. The Juvenile Lectures, at Christmas, will be given by Professor Henry E. Armstrong, Ph.D., F.R.S., the subject being a chemical one.

NOTES AND QUERIES.

*. Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Waterproofing.—Has there ever been written an article or a book on waterproofing? If so I shall be glad of the title of it, the author's name, and the price. The information is required in connection with an important work.—Dr. LORENZ.

MEETINGS FOR THE WEEK.

THURSDAY, Nov. 15th.—Chemical, 8. Ballot for the Election of Fellows.

TO CAPITALISTS.

The Inventor and Proprietor of a Valuable Medicine seeks a gentleman with capital to work his discovery. Letters Patent have been secured in Great Britain and America. Absolute proof of the value of this remedy will be given. Principals or their Solicitors only will be negotiated with.—Address "Patentee," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

NEW SOUTH WALES.

THE GOVERNMENT OF NEW SOUTH WALES intend to establish METALLURGICAL WORKS on a scale sufficiently large for determining, in bulk, the best methods of treating Ores produced in the Colony.

A SUPERINTENDENT is REQUIRED to erect, control, and direct these Works. He must possess the highest qualifications and widest experience, and it will be his duty to introduce the best methods of treating Ores, with a view to extract therefrom the metals and other substances possessing an economic value. He would also have to impart full instruction in the various methods of treatment, and to afford every facility to Smelters and Miners for acquiring a practical knowledge of the processes employed.

Applications, stating Candidate's age, accompanied by copies of testimonials, must be sent, on or before December 12, 1888, to the Agent-General for New South Wales, 5, Westminster Chambers, London, S.W.

SAUL SAMUEL.

Agent-General for New South Wales.

November 1, 1888.

FOR SALE.—THE CHEMICAL GAZETTE. Complete Set (unbound and uncut), 17 volumes; from November, 1842, to December, 1859.—Address, "Publisher," CHEMICAL NEWS Office, Boy Court, Ludgate Hill London, E.C

ELECTRO-CHEMISTRY.

Considerable attention is now being given to the use of Electricity in Chemical processes.

MESSRS. J. G. STATTÉR & CO., LIMITED, wind Dynamo Machines to suit the requirements of those engaged in Electro-Chemical experiments, and assist clients in selecting Electrical machinery suitable for their purposes. Correspondence invited. Estimates free.

J. G. STATTÉR and CO., Limited, ELECTRICAL ENGINEERS, ALLIANCE ENGINEERING WORKS, West Drayton, near London.

EMPTY PETROLEUM BARRELS.

THE KEROSENE COMPANY, LIMITED, are the largest purchasers of EMPTY PETROLEUM BARRELS in the United Kingdom.

Empties may be delivered for our account in LONDON to—Atlantic Wharf, Bow Common; Western Wharf, Old Kent Road; and on the River Thames to Thames Haven Petroleum Wharf, Thames Haven. We also receive Empties at the various Railway Depots in London.

LIVERPOOL.—To the order of Messrs. Samuel Banner and Co., 8, Fazakerley Street.

BARROW-IN-FURNESS.—To the order of the Barrow Petroleum Storage, Barrow-in-Furness.

We pay 1d. per Barrel more for Barrels branded with our own Brand, "LUSTRE," than for Barrels branded with American or other Russian or English Brands.

Before sending any further Empties to us will you please apply to us for labels, which we supply free. Such labels to be affixed to each Barrel by the sender, so that the Empties may be recognised and all disputes avoided.

DEDUCTIONS FOR DAMAGES.—Broken Head 1s.; Broken Stave or Chimb 6d. If Bung-hole exceeds $2\frac{1}{2}$ inches in diameter, 6d. If Taphole exceeds $\frac{3}{4}$, or if two tapholes in a Barrel, 6d. If the Glue be bad, 6d. For each Hoop off, 6d.

SPECIAL NOTICE.—As our Oil would be seriously damaged if put into Barrels that have contained Paraffin Oil, Paraffin Empties are useless to us, and we are compelled therefore to decline to receive them.

THE KEROSENE COMPANY, LIMITED,

(Capital, £300,000),

IMPORTERS OF RUSSIAN PETROLEUM.

LONDON (HEAD OFFICE)—26, Great St. Helens, E.C.

LIVERPOOL.—Messrs. Samuel Banner and Co., Agents, 8, Fazakerley Street.

BARROW-IN-FURNESS.—The Barrow Petroleum Storage.

COMPANY'S "ELBRUZ," carrying 23,500 Barrels of Oil.
TANK "KASBEK," " " " "
STEAMERS. "ARARAT," " " " "

These Steamers trade regularly between Batoum and London, Liverpool, and Barrow. The Russian Prince, carrying 23,500 barrels of oil, the Caucas, carrying 14,000 barrels of oil, and the Marquis Siciluna, carrying 13,500 barrels of oil, will also trade for account of the Company, so that a regular supply can be guaranteed.

WEGELIN AND HÜBNER, Halle-on-Saale, MACHINE WORKS AND IRON FOUNDRY.

Representatives: NICKELS & Co., 150, Holborn, London, E.C.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37,746,
with increased effect through abolishing the noxious spaces; best
Air-Pump for Compression and Evacuation; useful effect up to 90
per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment,
with Attachment for Filtration with Exclusion of Air; in Wood,
Iron, or Bronze every desired size

Experimental Filter Presses

in Wood, Iron or Bronze.

Filtration Experiments, if desired, carefully conducted in
our Laboratory).

Steam Pumps & Transmission Pumps,
horizontal, vertical, mounted on column, Wall Pumps, Pumps for
Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids.
"Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or
Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids,
any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof,
i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c.
Also Small Ice Machines for Families, Laboratories,
Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure,
or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Com-
pound Steam Engines.
From 2—150 horse-power

Steam Water Pumps,

newest, most approved Construction, taking up little room, and
especially suitable for placing in Wells, with great efficiency; up
to largest sizes.

Compressors driven by Steam or Belt,
for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon
Ether, Alcohol, Acetone, Water; in Iron or Copper. (Extraction
Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.
Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans,
and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin
Refineries, Resin Distilleries, Paraffin Works, Tar Dis-
tilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest
References for our above-named Specialities on
Application.

PETROLEUM JELLY,

EQUAL TO AND CHEAPER THAN VASELINE.

SANITARY FLUID AND SHEEP DIP,
THE CHEAPEST AND BEST DISINFECTANT.

GREASE, PITCH, ASPHALTE, AND ALL PRODUCTS OF TAR AND RESIN.

Samples and Prices on application.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1512.

EXISTENCE OF A VOLATILE ALKALOID IN PEPPER.

By WILLIAM JOHNSTONE, Ph.D., F.I.C., &c.

THE subject of this short note is to announce the existence or discovery of a volatile alkaloid in pepper possessing strong alkaline properties. The analysis of its platinum salt gave the following results:—

		Found.	Calculated.
C		120.0	20.02
H		24.0	4.32
N		28.0	5.01
Pt		197.4	33.93
Cl		213.0	36.62
$2(C_5H_{11}N.HCl)PtCl_4$	582.4	99.90	100.00

These results so closely agree with the formula of piperidine that I think I am justified in announcing the existence of piperidine in pepper.

I have made several estimations of this volatile alkaloid in various peppers, and find that nine samples of black pepper gave an average of 0.56 per cent, with a minimum of 0.39 per cent and maximum of 0.77 per cent calculated as piperidine.

Long pepper contains 0.34 per cent, and pepper refuse composed principally of the husks 0.74 per cent.

Three samples of white pepper gave respectively 0.34, 0.21, and 0.42 per cent, showing that the alkaloid is contained principally in the husk, and which naturally accounts for the greater pungency of black pepper over that of white pepper.

The same samples of black pepper were examined for piperine and the amount estimated, giving a maximum of 13.03 per cent, a minimum of 5.21 per cent, and a mean of 8.25 per cent.

ON BUMPING EBULLITION (SOUBRESAUTS).

By CHARLES TOMLINSON, F.R.S., F.C.S.

IN the CHEMICAL NEWS (vol. lvii., p. 244) was inserted a note from me on the above subject with reference to the recommendation of a German chemist to make use of pumice stone as a remedy for bumping. In the current number of the *Journal of the Chemical Society* an abstract is given of a paper by a Russian chemist, who recommends for the same purpose "a few very thin capillary glass tubes of [from] 3 to 10 m.m. in length, and sealed up at one end." The abstractor of the paper finds the suggestion "invaluable, especially for [qy. in.] the distillation of concentrated acids."

In January, 1869, I read a paper before the Royal Society "On the Action of Solid Nuclei in Liberating Vapour from Boiling Liquids." In this paper the whole subject of bumping ebullition is discussed, and the various proposed remedies practically examined, both as to success and failure. The value of porous bodies is insisted on, and estimated according to the increased amount of the distillate in distilling a variety of liquids. The practical value of these nuclei was further illustrated in a paper read before the Society of Arts on April 7, 1869, and printed,

together with the discussion that followed the reading, in the Society's *Journal*. A number of experiments were performed to illustrate the leading points. The subject was also brought before the Pharmaceutical Society on May 18 in the same year, and was fully reported in the CHEMICAL NEWS.

With respect to the use of capillary tubes, I quote the following passage from my paper in the *Journal of the Society of Arts*.

"I have already said that these porous nuclei act by the force of capillarity, and so powerful is this force alone that it can be applied in a variety of ways. Even a short bundle of fine capillary tubes, united, like a faggot, by a thread in the middle, is an active nucleus in liberating vapour. Such a bundle, weighing only ten grains, put into a retort from which methylated spirit was being distilled, raised the amount of distillate in the ratio of 100 : 110."

The Russian chemist finds that charcoal acts only for a short time in preventing bumping. This may be the case with ordinary wood charcoal, but it is not so with well-prepared boxwood, or still better with cocoanut-shell charcoal, which will continue active for hours, and even days, making the boiling easy, and increasing the amount of the distillate. For example:—Methylated spirit, boiling at 171° F., distilled in a glass retort, gave 244 grains in five minutes, but when three or four fragments of boxwood and cocoanut-shell charcoal, weighing together 20 grains, were added, the distillate, in five minutes, weighed 325 grains, or as 100 : 133.2.

Highgate, N., Nov. 9, 1888.

ADULTERATION OF COAL-TAR NAPHTHA.

By THOMAS T. P. BRUCE WARREN.

COAL-TAR naphtha, as used by indiarubber manufacturers, is obtained, generally, from the crude products of the gas-works. There is no doubt a great deal obtained in the "carbonising process," used in preparing coke for smelting operations, which does not appear in commerce under a distinct name, although such naphtha is not unknown.

Generally, Newcastle or Cannel coal, or mixtures of these, are used in making coal-gas; hence the tar met with will vary more or less, and consequently the naphtha. The process of destructive distillation will introduce a variation in the composition of the naphtha recovered from such tar.

Petroleum products are now largely mixed with coal-tar naphtha. The advantages are that their greater volatility enables the spreading machines to be driven at three or four times the speed, whilst the diminished cost is greatly in its favour.

The low iodine absorption of petroleum and its commercial products, as compared with naphtha obtained from Newcastle coal, or mixtures used in gas-making, will readily reveal the fraudulent admixture of petroleum.

In the fractional distillation of such a mixture it is very important to examine each product.

SOME CURIOUS PROPERTIES OF METALS AND ALLOYS.*

By Professor W. CHANDLER ROBERTS-AUSTEN, F.R.S.

THE lecture consisted mainly of experimental demonstrations of the changes induced in metals, either by slight variations in the treatment to which they are subjected

* Abstract of a Lecture delivered before the Royal Institution of Great Britain, May 11, 1888.

or by rendering them impure by the addition of small quantities of metals or metalloids.

Prof. Austen began by pointing out that for centuries the early metallurgists investigated the action of exceedingly small quantities of matter upon masses of metal, and he said that, strange as it may seem, the promulgation, in 1803, of Dalton's atomic theory threw a flood of light upon chemical phenomena, but cast into shade such investigations as those of Bergman which dealt with influences of "traces" upon masses, and the authority of Berthollet was not sufficient to save them from neglect. In this eventful year for science, 1803, the latter published his essay on chemical statics, in which he stated, as a fundamental proposition, that in comparing the action of bodies on each other, which depends "upon their affinities and mutual proportions, the mass of each has to be considered."* His views were successfully contested by Proust, but, as Lothar Meyer says, the influence on chemistry of the rejection of Berthollet's views was remarkable: "All phenomena which could not be attributed to fixed atomic proportions were set aside as not truly chemical, and were neglected. Thus chemists forsook the bridge by which Berthollet had sought to unite the sister sciences, physics and chemistry." Fortunately, however, in this country there was one chemist who had followed up the line of work indicated by the early metallurgists, for in 1803, the same year as that in which both Berthollet's essay and Dalton's atomic theory were published, Charles Hatchett† communicated to the Royal Society the results of a research which he had conducted, with the assistance of Cavendish, in order to ascertain "the chemical effects produced on gold by different metallic substances when employed in certain" (often very small) "proportions as alloys."

Allusion was then made to the evidence of the passage of metals into allotropic states, and it was shown that although the importance of the isomeric and allotropic states was abundantly recognised in organic chemistry, it had been much neglected in the case of metals. Special attention was then devoted to the work of Joule and Lyon Playfair, who showed, in 1846, that metals in different allotropic states possessed different atomic volumes, and the lecturer then proceeded to the consideration of the work of Matthiessen who, in 1860, was led to the view that in certain cases when metals were alloyed, they passed into allotropic states, probably the most important generalisation which has as yet been made in connection with the molecular constitution of alloys.

Instances of allotropy in pure metals were then shown to the audience, such, for example, as Bolley's lead which oxidises readily in air; Schützenberger's copper; Fritsche's tin, which fell to powder when exposed to an exceptionally cold winter; Gore's antimony; Graham's palladium; and allotropic nickel. It was further shown that metals could be obtained in chemically active states under the following conditions:—Joule proved that when iron is released from its amalgam by distilling away the mercury the metallic iron takes fire on exposure to air, and is therefore clearly different from ordinary iron, and is, in fact, an allotropic form of iron. Moissan‡ has shown that similar effects are produced in the case of chromium and manganese, cobalt, and nickel, when released from their amalgams with mercury.

Evidence is not wanting of allotropy in metals released from solid alloys, as well as from fluid amalgams with mercury. Certain alloys may be viewed as solidified solutions, and when such bodies are treated with a suitable solvent, usually an acid, it often happens that one constituent metal is dissolved, and the other released in an insoluble form. Reference was then made to a new alloy of potassium and gold, containing about ten per

cent. of the precious metal. If a fragment of this alloy be thrown upon water, the potassium takes fire, decomposes the water, and the gold is released as a black powder; there is a form of this black or dark brown gold which appears to be an allotropic modification of gold, as it combines with water to form auric hydride. By heating this dark gold to dull redness, it readily assumes the ordinary golden colour. The Japanese use this gold, released from gold-copper alloys, in a remarkable way, for they produce, by the aid of certain pickling solutions, a beautiful patina on copper which contains only two per cent. of gold, while even a trace of the latter metal is sufficient to alter the tint of the patina.

With regard to theoretical views as to molecular change in metals, special care was given to a description of the work of Professor W. Spring, of Liège, who had furnished much evidence in support of the view that polymerisation of metals, that is the rearrangement of atoms in their molecules, could take place even in *solid* alloys of lead and tin.

With reference to the passage of metals into allotropic states under slight external influences, it was stated that Debray* has given a case of an alloy in which a simple elevation of temperature induces allotropic change in the constituent metals. It is prepared as follows: ninety-five parts of zinc are alloyed by fusion with five parts of rhodium, and the alloy is treated with hydrochloric acid, which dissolves away the bulk of the zinc, leaving a rich rhodium-zinc alloy, containing about 80 per cent. of rhodium. When this alloy is heated in *vacuo* to a temperature of 400° C., a slight explosion takes place, but no gas is evolved, and the alloy is then insoluble in *aqua regia*, which dissolved it readily before the elevation of temperature caused it to change its state. We are thus presented (as the experiment shown to the audience proved) with another undoubted case of isomerism in alloys, the unstable, soluble modification of the alloy being capable of passing into the insoluble form by a comparatively slight elevation of temperature.

The industrial importance of the passage of metals and alloys into allotropic states, and the possibility of changing the mechanical properties of metals by apparently slight influences, was fully dealt with, and the lecture concluded with a detailed description of Professor Austen's own experiments which have since been printed in the *Philosophical Transactions* of the Royal Society, the results showing that very small amounts of metallic impurities exert an extraordinary effect on the tenacity and extensibility of gold, and that small as the amounts of these impurities are, their influence is rigidly controlled by the Periodic Law of Newlands and Mendeleeff, the deleterious action of a metallic impurity being in direct relation to its atomic volume. The audience was asked "to remember that the knowledge of the kind of facts which had been considered comes to us from very early times, for the influence produced on metals by small quantities of added matter had a remarkable effect on the development of chemistry, mainly by sustaining the belief of the early chemists in the possibility of ennobling a base metal so as to transmute it into gold. This was the object to which they devoted life and health, and laboured with fast and vigil. We inherit the results of their labours, and their prayers have been answered in a way they little anticipated, for, from an industrial point of view, if not from a scientific one, metals are 'transmuted' by traces of impurity. Possibly we are nearing an explanation of the causes which are at work, but the fact remains that iron may be changed from a plastic material, which in ornament can be fashioned into the most dainty lines of flow, into one of great endurance, to which, for the present at least, the defence of the country may be trusted, apparently because armour-plates and missiles owe their respective qualities to the fact that carbon, manganese, and chromium have small atomic volumes."

WAVE-LENGTHS OF METALLIC SPECTRA
IN THE ULTRA VIOLET.*

By JOHN TROWBRIDGE and W. C. SABINE.

PART I.

Introduction.

THE Catalogue of Metallic Spectra, revised by the Committee of the British Association, and published in its volumes for 1885 and 1887, is an extremely valuable contribution to the subject of spectrum analysis; it contains the material for future generalisation in regard to the molecular structure of so-called elements, or in regard to the harmonic relations which may exist between their wave-lengths. Here can be found in juxtaposition the results of various observers upon the metallic spectra of the same metal, and the student can judge of the relative accuracy of the results. A superficial inspection of this Catalogue will show that even distinguished observers, like Thalen and Kirchhoff, often differ in their results by one part in 4000, or one part in 2500. No observer of metallic spectra gives results to more than one-tenth of Angstrom's unit, or to more than one-tenth of one wave-length. Physical science, however, now demands a greater degree of accuracy. Various hypotheses in regard to the apparent coincidences between lines of metallic spectra and lines in the solar spectrum have been propounded, and can only be settled by more accurate measurements of wave-lengths. There are also questions constantly arising in regard to the displacement of lines of spectra due to the motion of the stars and to changes of temperature, which require a greater degree of accuracy in the measurement of wave-lengths of gaseous and metallic spectra than the results of previous observers afford. It may be remarked, that observations upon the metallic spectra of metals from the limits of the visible red to the limits of the visible violet have become comparatively easy; for the solar spectrum can be used to identify the lines of the metals and to ascertain their wave-lengths. It is only in the extreme infra red region and in the ultra violet that observations become difficult. In these regions we must trust to photography to reproduce by long exposures of the sensitive plate the feeble lines of metals which may manifest themselves there. In the infra red region, as far as wave-length 10,000, it is possible to photograph the solar lines, and we can compare the spectra of such metallic lines as may exist between the A line and the limit 10,000 with the solar spectrum. Beyond this limit, and beyond wave-length 2800 in the violet, the solar spectrum disappears, and the problem of measuring the wave-length of metallic lines which extend beyond these limits becomes a difficult one.

Besides the resolution of the difficulty of measuring the wave-lengths of the invisible rays of light with proper accuracy, the measurement of such wave-lengths is destined to prove a crucial test for various theories which must arise in the progress of physical science. The lines of the metals are exceedingly numerous in the ultra violet region, far more so than in the infra red region. If there are any harmonic relations between the wave-lengths of the spectra of metals, it is here that one might expect to observe such relations. Indeed, Professor Grünwald of Prague has lately enunciated a remarkable hypothesis upon the relations between the wave-lengths of so-called elements, and finds in the observations of various observers in the ultra violet a strong confirmation of his hypothesis. In any theoretical work upon the grouping of spectral lines, it is of fundamental importance that the wave-lengths of the lines should be determined with as great accuracy as possible. The coincidence of metallic lines with solar lines is at the best a doubtful piece of evidence. This evidence is of moment only when the number of coincidences becomes great, and is accompanied by characteristic grouping. A mistake of a wave-length in

the question of position is sufficient to destroy the support which the author of any hypothesis might claim for it.

Conditions for Accuracy of Measurement.

All measurements of wave-lengths hitherto published have been made by the old method of angular measurements with a spectrometer. We say old, for the use of Rowland's concave grating with its peculiar mounting must be characterised as a new method and a new departure in measurements of wave-lengths. The observation of wave-lengths of metallic spectra by the eye is most laborious, and the photographic plate must be substituted for the eye for most purposes. The angular positions of the spectral lines on such a plate assume great importance, for upon these positions depend the value of the wave-lengths. In the operation of photographing spectral lines it is necessary to substitute for the observing telescope and micrometer eye-piece of the spectrometer a camera box provided with a suitable lens and with a plate holder for the photographic plate. Unless the latter is small the spectrum will not be in focus on all parts of the plate; moreover, unless the distance of the photographic plate from the diffraction grating employed is comparatively large, the distances between the spectral lines on the photograph will not be proportional to wave-lengths. To determine these wave-lengths recourse must be had to various devices. The one usually employed is due to Cornu, and can be found described in the *Annales de l'Ecole Normale*, 2 série, tom. iii., p. 421; also in *Journal de Physique*, x., 1881, p. 425. It consists in photographing images of the slit of the spectroscop upon the photographic plate by turning the graduated circle of the spectrometer through measured angles. These photographic images serve as fiducial marks, by means of which wave-lengths of spectral lines on the plate can be calculated. In the case of diffraction spectra obtained by deflecting a bundle of parallel rays at the angle of incidence, i , with a deviation of order n , Δ_n is connected to the wave-length λ , and with a certain constant, a , of the grating by the formula—

$$2n \sin \frac{\Delta_n}{2} \cos \left(i - \frac{\Delta_n}{2} \right) = n\lambda.$$

It is evident that at least two errors can arise in the use of this formula; one from defective graduation of the circle of the spectrometer; another from the process of referring from the photographs of the slit on the plate to the photographs of the metallic lines.

We select the work of Hartley and Adeney* as perhaps the best type of this method of using a camera with a spectrometer. Their work is characterised by great care and thoroughness, and no one could probably attain better results by the use of a flat grating, with its concomitants of collimator, photographing lens, and camera. These observers state that they were not troubled by the underlying spectrum of a higher order than that which they photographed, for it was not brought to a focus with the latter. In the new method we propose to illustrate, all the spectra are in focus together, and this fact, instead of being an obstacle, can be turned to great advantage. In the absolute measurements of the wave-length of light, the spectrometer method with eye observation and with a micrometer is unquestionably more accurate than any photographic method. We have in this determination to deal with comparatively large quantities, and with well defined directions, which can be made to coincide with optical axes of the instrument; this is not the case, however, with the majority of the spectral lines on a photographic plate placed in a camera, which replaces the observing telescope of the spectrometer. The photograph contains possible errors, and any shifting or movement of the spectrometer circle to determine intervals on the photographic plate is apt to introduce other errors.

* Contributions from the Jefferson Physical Laboratory.

* *Philosophical Transactions*, clxxv., 1884, pp. 63-137.

The ideal arrangement would seem, therefore, to be a photographic apparatus which should remain in focus for all the spectra of the different orders, in which distances between successive lines on the photographs of the spectra should be closely proportional to wave-lengths, so that, the constant being known for a certain position of the sensitive plate, the wave-lengths can be determined by simple linear measurement. Moreover, it is desirable, as we have said, that the underlying spectra should be brought to the same focus as the overlying; for by this means we can compare the wave-lengths of lines in the spectra of different orders, and halve our errors. It is true that some confusion results from having the metallic lines in the spectra of different orders photographed upon the same plate; but a little experience enables one to separate the lines with comparative ease, and the gain in accuracy compensates for the additional trouble.

The apparatus which best answers the requisitions we have pointed out is that of the concave grating of Rowland, with its peculiar mounting, which has been fully described in the *American Journal of Science*, vol. xxvi., 1883, p. 87.

Objects of the Present Investigation.

The conclusion of the work of the Committee of the British Association on the tabulation of metallic spectra seemed to us to require a survey of the work, which must be done in the future in order to perfect and correct the work of the past. We have therefore examined the tables given by the committee in order to see what lacunæ could be supplied, and to point out the directions for routine work which may afford material for future generalisations. In the pursuance of this work, we have been compelled to examine the accuracy of measurements of wave-lengths hitherto made in the ultra violet. With the aid of the new Map of the Solar Spectrum published by Professor Rowland, it is very easy to determine the wave-length of metallic lines in the visible spectra of metals; for it is merely necessary to photograph a portion of the solar spectrum upon the same plate as that which receives the spectra of the metals under consideration, and then to refer to the published map. We have already remarked, that even a superficial examination of hitherto published catalogues of wave-lengths of metallic spectra will show that distinguished observers differ in their determinations by one or two wave-lengths. The task of re-measuring the wave-lengths of metallic lines is a very great one, and approaches in character the routine work now prosecuted in astronomical observatories in the re-determination of star places, the photometric intensities of stars, and the classification of star spectra. In our present work we have confined our attention to ultra violet spectra. Since the solar spectrum disappears in the neighbourhood of wave-length 2800, the task of identification of wave-lengths becomes a very serious one. To replace the solar spectrum we must refer the lines of metallic spectra to carefully measured lines of certain metals. When one metal ceases to give spectral lines another must be selected. To test the relative accuracy of what we have termed the old method of measurement with that of the new, we have measured the lines of electrolytic copper, and have compared our results with those of previous observers in regard to the distribution of errors. Besides the comparison of accuracy, we have examined the limit of the spectra of copper in the ultra violet, in order to see if that given by previous observers could be extended.

Apparatus.

The apparatus consisted of a concave grating of 21 ft. 6 in. radius, mounted in the manner described by Professor Rowland. The camera was provided with a shutter, which enabled us to expose different portions of the sensitive plate at pleasure. An alternating dynamo machine was employed, together with a Ruhmkorff coil. The alternating machine gave from eight to ten thousand

reversals per second. With a battery of from six to ten two-quart Leyden jars, a powerful spark was obtained between the metallic terminals which we employed. The spark was produced close to the slit of the apparatus, and the time of exposure varied from one to two hours. At various times endeavours were made to substitute the more powerful light of the carbon electric light for the electric spark, in the hope of shortening the time of exposure; but these efforts were not successful. If they had been, we should have been obliged to struggle with the question of impurities in the carbons. An exposure of fifteen minutes to the ultra violet spectra of metals burned in the electric light produced no image below wave-length 3000. A quartz condensing lens was employed with the arc light, and therefore no light was lost by selective absorption. With the spark no lens was necessary.

By curving the photographic plate, all parts of it remain in focus, and distances on the plate are closely proportioned to wave-lengths. Calling Y = wave-length, we have $Y = C + \alpha x$, where C and α are constants, and x is the distance along the plate.

The determination of the wave-lengths of lines extending over a range of three hundred tenth metres involved the taking of three negatives. The sensitive dry plate (2×10 inches) was pressed by springs against the "forms" of the plate-holder into an arc of a circle. Having placed the plate-holder on the camera box, the girder bearing the camera and grating was moved along its tracks until the position of the pointer of the carriage on the scale beside the track indicated that light of wave-lengths 4200 to 4800 in the first spectrum and 2100 to 2400 in the second spectrum would fall on the plate. The shutter was turned so as to expose only the lower half of the plate, and a photograph of the solar spectrum from 4200 to 4800 taken. The shutter was again turned, and the upper half of the plate given a long exposure to the light of the spark. Both spectra were in focus. The wave lengths of the metal lines were then found directly by interpolation on the normal spectrum, from the solar lines whose values were given in Rowland's Photographic Map and table of wave-lengths.* The interpolation was made by means of measurements on a dividing engine. In order to correct for any displacement due to the motion of the spark from side to side, or to jarring arising from the great noise of the spark, and also in order to sift out the lines belonging to the first spectrum from those belonging to the second, the girder was moved to the violet of the third, with its magnified dispersion and different underlying spectra. The metal and solar lines were taken side by side, and the interpolation for the wave-lengths of the metal lines made as before. From this the correction to be applied to the previous plate was found, amounting in some cases to 0.2 of a tenth metre. The correction thus found was applied to all of the lines on the plate. The girder was now moved so that the sensitive plate was in the extreme ultra violet of the first spectrum, and the plate exposed to the light from the spark. From this negative the value of the wave-lengths of the faint lines were obtained by interpolation from the values of the stronger lines as determined by the first plate. It also served as the final test whether the lines on the first negative were of the first or second order. All of the lines more refrangible than line 2123.1 were, in the case of copper, found from this negative and from line 2136.1 by direct measurement.

Another method of distinguishing which lines on the first negative belong to the second and which to the first spectrum, is to place in front of the slit, while taking the metal lines, a piece of plane glass. The second spectrum for this refrangibility will be completely cut out, and only the metal lines of the first remain, being in the visible violet.

The only source of error was in the setting of the microscope upon the broad or faint lines. The probable

* *American Journal of Science*, March, 1887.

error of this is about 0·1 tenth metre. For the few most refrangible lines it may be greater.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, November 1st, 1888.

Mr. WILLIAM CROOKES, F.R.S., President, in the Chair.

MESSRS. James Schleselman and Henry A. Miers were formally admitted Fellows of the Society.

Certificates were read for the first time in favour of Messrs. Charles M. Adams, 29, Mosley Street, Newcastle-on-Tyne; John Hope Belcher, B.A., Craigmount, Edinburgh; Percy Carter Bell, The Cliff, Higher Broughton, Manchester; William Berry, Hampton Park, Redland, Bristol; William D. Bohm, 51, The Avenue, Acton; Frank Bower, 37, Lansdowne Road, Clapham Road, S.W.; James E. Brunker, Minore, Saint Kevin's Park, Rathmines, Dublin; George Alexander Byrn, Technical College, Sydney; John Morrow Campbell, 22, Regent Moray Street, Glasgow; Vaughan Cornish, B.Sc., High School, Newcastle-under-Lyme, Staffs.; William Douglas, A.I.C., Diamond, Demerara; Arthur G. Everard, North Street, Bishop's Stortford, Herts; Henry Forth, 1, Beech Avenue, Sherwood Rise, Nottingham; Frederick B. Guthrie, 65, Portland Road, Notting Hill, W.; John Lawrence Van Guyzel, Indian Medical Service, Madras; John Hansfield, Waterfoot, near Manchester; Urban Arthur Jackson, 2, New Bridge Street, Strangeways, Manchester; Alfred Battye Knaggs, Ebor Mount, Huddersfield; Oscar Lowman, B.A., Ph.D., 66, West 8th Street, Cincinnati, Ohio; William Marshall, The Baths, Saint Andrews, N.B.; George Edward Perry, 6, Norward Villas, Edgbaston, Birmingham; Hubert Naylor Bardsley Richardson, Elmfield, Knighton, Leicester; John S. Rigby, Bagot Street, Liverpool; John Sanderson, 57, Belsize Park Gardens, London, N.W.; Thomas Oliver Landolt, Baron's Court Road, West Kensington; William Jay Schieffelin, Areis Strasse, 1, Munich; Arthur Landaner Stern, Bass & Co's. Old Brewery, Burton-on-Trent; William Taylor, Hong Kong; Charles Turner, 25, Sidney Street, Cambridge; J. T. Ainslie Walker, Hope Cottage, Winchburgh, Linlithgowshire; Edward Dalrymple Walrond, B.A., North Eastern County School, Barnard Castle, Durham; Frederick Walmesley Warrick, 136, Southampton Row, W.C.; Edward J. Way, Transvaal Gold Exploration Company, Transvaal; Ernest William Whieldon, 42, Worthingham Road, East Dulwich; R. W. Woosnam, York House, Southend-on-Sea.

The following papers were read:—

72. "The Constitution of the Terpenes and of Benzene." By WILLIAM A. TILDEN, D.Sc., F.R.S.

With the object of testing further the current hypothesis concerning the constitution of the terpenes, the author has made a series of quantitative estimations of the amount of paratoluic acid produced by the oxidation of several of the terpenes with dilute nitric acid in comparison with the amount of the same product formed under the same conditions from cymene and from paraxylene. The following results were obtained:—

100 parts by weight give of paratoluic acid—	
Cymene (from turpentine)	80·1
Cymene (from cumin oil)	73·1
Paraxylene (Kahlbaum's)	77·2
Australene from American turpentine	1·2
Terebenthene from French turpentine	1·9
Hesperidene from orange oil	0·0
Dipentene from C ₁₀ H ₁₆ ·2HCl obtained from terpin	27·6

An experiment on a larger scale with hesperidene showed that the chief product of its oxidation by nitric acid is oxalic acid: Using chromic acid mixture, Wright and Beckett found that acetic acid was the only product.

The characteristic properties of the terpenes as a class—the readiness with which they polymerise by heat or contact with a small quantity of sulphuric acid, the eagerness with which they combine with bromine, with hydracids, and in some cases with the elements of water, and the nature of their products of oxidation—are such that they differ wholly from all known benzenoid hydrocarbons.

In order to settle the limit of the combining capacity of the chief terpenes about which there is some difference of statement on the part of different authors, the amount of bromine taken up by the hydrocarbon was determined. From the several experiments made in each case the following numbers were deduced.

136 parts or 1 mol. proportion of the hydrocarbon combines with the following quantities of bromine:—

Australene.	313
Terebenthene	307
Hesperidene	322
Dipentene (terpilene)	297
Calculated for Br ₂	160
" " 2Br ₂	320

In all cases the hydrocarbon unites with four atoms of bromine and no more. Camphene does not combine with bromine and hence must be regarded as saturated in the usual sense.

Since the terpenes possess at most four units of available combining capacity, the nucleus of six carbon atoms, which they all undoubtedly contain, cannot be supposed to form an open chain. They must be united into a closed chain containing at the most two double bonds. Hence formulæ of the character of those proposed originally by Oppenheim, and later by Goldschmidt and Zurrer, by Wallach and Brühl are the most probable. Such formulæ represent the molecule as constructed upon the basis of a ring of six carbon atoms disposed in the manner which has been so long familiar in Kekulé's formula for benzene. But since the terpenes are certainly not benzene-derivatives, Kekulé's formula must be abandoned. The evidence in support of this conclusion is not derived solely from the foregoing considerations; which standing alone would probably be regarded as inconclusive. The chief objection which has been urged against Kekulé's formula is based upon the difference in the nature of the link between the carbons which stand in the relative positions 1:2 and 1:6. The hypothesis devised by Kekulé himself to meet this difficulty cannot be regarded as satisfactory. Another objection to the symbol is that benzene is represented as containing "ethylenic" carbon, for which there is no evidence at all; moreover a body of this formula when treated with nitric acid ought to yield abundance of oxalic acid: this the terpenes do, but the benzenoid hydrocarbons do not.

The characteristics of the benzenoid hydrocarbons and their derivatives may be explained by the formulæ proposed by Claus, by Ladenburg, and by Armstrong and von Baeyer, but at present there is not sufficient evidence to enable us to decide between them.

As to the terpenes, the conclusions derived from their refraction equivalents are so much at variance with the chemical behaviour of many members of the group that they cannot be accepted without considerable qualification. Such other physical evidence as is deducible from the work of Hartley, and of Abney and Festing, tells entirely against the assumption that the terpenes are derivatives of benzene.

DISCUSSION.

Referring to Professor Tilden's statement that it was an objection to Kekulé's formula that benzene did not yield oxalic acid on oxidation, Dr. JAPP said that phenol

he believed, gave a considerable quantity of the acid on oxidation with alkaline permanganate.

Mr. GROVES added that oxalic acid was obtained in quantity on oxidation of chloranilic acid; and Dr. PERKIN remarked that he had obtained a quantity of oxalic acid in preparing picric acid from phenol.

Dr. PERKIN said that the magnetic rotatory power of American turpentine was remarkably low, which was a probable indication of the non-existence of a C_6 nucleus.

Dr. ARMSTRONG expressed the opinion that the evidence at disposal was entirely insufficient to enable us to determine the constitution of the terpenes with any degree of probability. He could not accept Dr. Tilden's conclusion that camphene was saturated, as it readily united with a molecular proportion of hydrogen chloride. With regard to the constitution of benzene, his main contention was that the cross connexion of carbon atoms exhibited in Claus's and similar formulæ was inconceivable; he believed that corresponding carbon atoms could exercise an influence upon each other although unconnected except indirectly.

Professor TILDEN said that his chief object in referring to the constitution of benzene was to emphasize his opinion that whatever the nature of the combination between the carbon atoms, it did not correspond to that which obtained in ethylene.

73. "*Some New Compounds of Magnesia with the Halogens: A Contribution to the Study of the Electrolysis of Magnesium Chloride Solution.*" By C. F. CROSS and E. J. BEVAN.

Their observations on the electrolysis of magnesium chloride in aqueous solution, which is now a process of preparing bleaching solutions on the large scale, had previously made the authors aware that the decomposition was attended by interactions *not* to be explained on the view commonly held, viz., that the ions are magnesium and chlorine, which by secondary interactions give rise to magnesia and hypochlorous acid.

With the view of elucidating the actual mechanism of the electrolysis, the authors have studied in the first instance the phenomena at the cathode. The white substance separated under the condition that the solution is not kept in circulation, is not magnesia (hydrate), but a chloroxygen compound of magnesium, in which the ratio of Cl to total oxidising power expressed as Cl is approximately 1 : 2. It may be regarded, therefore, as a magnesium hypochlorite. It is worthy of note that the percentage weight of "total oxidising Cl" lies between 30 and 35, calculated on the anhydrous substance. The compounds described were analysed in the freshly prepared and hydrated condition. They differ from the normal magnesium hypochlorite not only in being insoluble, but also in point of their stability.

Similar compounds were obtained on electrolysis solutions of magnesium bromide and magnesium iodide, though in the case of the latter the ratio—total oxidising iodine : iodine as silver iodine—is considerably less than 2, viz., approximately 6 : 5. Nevertheless, the compound decomposes ammonia with evolution of nitrogen, and is in all its properties rather a compound than a mixture of iodine with magnesia.

The authors are engaged in studying the phenomena to be observed at the anode during the electrolysis in question, and the composition of the resulting solution in regard to the whole of the chloroxygen compounds, of which there appear to be at least two.

74. "*The Heat of Dissolution of Various Substances in Different Liquids.*" By S. U. PICKERING.

The author has explained the constancy of the heat of neutralisation of acids by alkalis on the view that the affinity of the radicles composing the salt molecules concerned is not entirely saturated by their combination, and that the residual affinity of one of these radicles becomes in each case entirely saturated by the solvent. The heat of combination of the atoms, and the heat of dissolution

of the molecules which they form, are thus parts of the same operation, and must therefore both be chemical in their nature. Dr. Nicol has suggested the possibility of the heat of dissolution of the molecules of four solids showing the relation expressed by—

which would render the above-mentioned connexion between the heat of dissolution and formation of the molecules unnecessary. The author shows that if Dr. Nicol's suggestion held good a certain relationship would obtain between the heat of dissolution of two pairs of salts in two different liquids. To investigate this he has determined the heat of dissolution of the nitrates and chlorides of calcium and lithium in water and in alcohol, and has found that they give results showing a difference of 4461 cal., where, according to Dr. Nicol's view, there should be no difference at all.

Other salts were also examined and it was found that the heat of dissolution in alcohol was sometimes greater and sometimes less than in water.

According to the author's views the heat of dissolution should be the same whatever the solvent were, provided (1) that the residual affinity of one only of the radicles constituting the dissolved substance be saturated by the solvent, and (2) that the saturation be effected by *free* affinity of the solvent, i.e., that no alteration in the force with which the molecules or atoms of the solvent are united together be involved. The first condition is ensured by taking an elementary substance instead of a salt; and the author has found that the heats of dissolution of iodine and bromine in various liquids give much more nearly identical results than salts do, and that with liquids containing no oxygen the results are identical within experimental error. Oxygenated liquids give higher results, and the presence of sulphur as a constituent element of the solvent has, to a certain extent, the same effect as oxygen. If the second as well as the first above-mentioned conditions could be secured, the results would probably be in all cases identical.

DISCUSSION.

Professor RAMSAY said it appeared that the heats of dissolution of iodine in various media might be arranged in two well-defined groups. Might not this be correlated with the fact that iodine dissolves in certain liquids forming a brown solution, and in others forming a violet solution; and with the observation recently made by Loeb that iodine existed in these differently coloured solutions in different molecular states.

75. "*The Criteria of Plane and Axial Symmetry.*" By HENRY E. ARMSTRONG.

Wislicenus, in his now widely known paper on the space arrangement of the atoms in carbon compounds,

a.C.b

has termed compounds of the form $\parallel$ axially symmetric, b.C.a

a.C.b

and those of the form $\parallel$ plane symmetric. In allo- a.C.b

cating these formulæ he has argued in a case such as is afforded by the two tolane dichlorides, for example, that the compound of higher melting-point (143°) is necessarily the plane symmetric modification, as it is produced on chlorinating tolane—

and he urges that this conclusion derives support from the behaviour of tolane tetrachloride on reduction. Of the three possible configurations which this compound may acquire, viz. :—

he regards the first and second as far the most likely to

exist especially at low temperatures; both would furnish on withdrawal of two corresponding chlorine atoms the same axially symmetric tolane dichloride, and it is therefore to be supposed that the modification formed in larger quantity on reducing the tetrachloride would be this modification. According to the recent experiment of Blank (*Annalen*, ccxlviii., 1), the two isomeric dichlorides are obtained nearly in the proportion of two parts of that of lower melting-point (63°) to one of that of higher melting-point; and the axially symmetric structure is therefore, it would seem, as a matter of course, assigned by him to the compound of lower melting-point.

The first argument is only valid provided that at the moment of change no isomeric change supervenes, and must be accepted with reserve—if not regarded as altogether untrustworthy—as further study of the changes involved in the production of isomeric compounds appears to make it more and more probable that the final product is very frequently the product of an unperceived isomeric change (cf. *Proceedings*, 1887, Abstr. Nos. 99—101; 1888, Abstr. Nos. 50 and 51).

The second is not an argument based on clearly ascertained facts, but derives its force entirely from hypothetical views as to the relative affinities of the radicles present in a compound, and the effect on the ultimate configuration which these affinities would have, and is especially based on the conventional assumption that dissimilar radicles would tend to influence and attract each other more than would similar radicles. But it is to be remembered that we have little certain knowledge of the relative affinities of different radicles, especially of similar as compared with those of dissimilar radicles; indeed, that our views are not based on the study of the radicles themselves, but are mere inferences from the apparent behaviour of the radicles in their compounds. Moreover, Thomsen's observations on the heats of combustion of chlorine compounds may be held to some extent to favour a view contrary to that put forward by Wislicenus (cf. *Phil. Mag.*, 1887 [5], xxiii., 106).

The most important argument averse to the interpretation given by Wislicenus, however, is to be found in the fact that in cases in which the constitution may fairly be regarded as established, the relation between configuration and physical properties is of the obverse order to that indicated by Wislicenus. Thus in the case of benzene di-derivatives the symmetric or para-derivative has always the highest melting-point; the same appears to be true of the symmetric tri- and tetra-derivatives; and in the case of naphthalene, in a series of isomeric di-derivatives, the axially symmetric modification is always that of highest melting-point, thus—

Again, of the four known naphthalene-disulphonic chlorides, the axially symmetric $\alpha'\alpha''$ modification melts at 183° , the dissymmetric $\alpha\beta$ modification at 128° , the axially symmetric $\beta^2\beta^2$ modification at 226° , and the plane symmetric $\beta^2\beta^2$ modification at 160° .

Employing the argument from analogy, it is therefore probable that the tolane dichloride melting at 143° is the axially symmetric, and that melting at 63° , the plane symmetric modification, and also, for example, that elaidic acid—and not oleic acid as Wislicenus assumes—has the "axial" structure. In the case of maleic and

fumaric acids, the argument here relied on would support the conclusion already arrived at by Van't Hoff and accepted by Wislicenus, which, however, is based not on geometric considerations, but on the observed property of maleic acid to form an anhydride.

It is a noteworthy fact that the majority of "allo-isomerides"—to use a term which is sufficiently expressive while it does not beg the question as to the determining cause of the isomerism—are compounds containing unsaturated carbon, usually in association with one of the halogens or oxygen. It does not appear that this circumstance has yet been taken into account, or that the extent to which the peculiarities manifested by the negative elements are concerned in and may condition the isomerism has been in the least considered. The symbolic system introduced by Van't Hoff and adopted by Wislicenus tends to withdraw attention from the consideration of the possible effect of the peculiarities referred to, inasmuch as a "double bond" is represented as the precise equivalent of two, and a treble bond as that of three single bonds; which all observations show is a misrepresentation of the facts.

76. "*Derivatives of Methylindole.*" By H. G. COLMAN, Ph.D., B.Sc.

By the action of sodium hypobromite solution on methylindole or methylindole-carboxylic acid, Fischer and Hess (*Ber.*, xxii., 561) obtained a brominated compound which on treatment with alkali yielded methylpseudisatin.

It is shown that the brominated substance is dibromomethyloxindole, a white crystalline substance melting with decomposition at 204° .

If sodium hypochlorite be substituted for sodium hypobromite, the corresponding dichloromethyloxindole is obtained m.p. 145 — 147° . Both compounds on boiling with alkali, or better with water, yield methylpseudisatin. The phenylhydrazones and oxime of the latter have been prepared: they are yellow crystalline compounds melting at 145 — 146° and 180 — 183° respectively.

By the reduction of dibromomethyloxindole in acid solution, monobromomethyloxindole and methyloxindole are successively obtained. Both are white crystalline compounds, the former melting at 132 — 134° , and the latter at 86 — 88° .

Methylpseudisatin, on reduction in acid or alkaline solution, yields methyldioxindole; this crystallises from benzene in needles or prisms melting at 149 — 151° .

77. "*Acetamide and Phenanthraquinone.*" By ARTHUR T. MASON, Ph.D., F.I.C.

The author finds that when oximide is heated in sealed tubes with glacial acetic acid at 220 — 230° C., acetamide is formed, which, however, on re-crystallisation from ether or benzene totally loses the peculiar smell of mice excrement which has hitherto been supposed to be its principal characteristic. Ordinary acetamide prepared by the distillation of ammonium acetate also becomes odourless by twice rectifying and rejecting the first portions of the distillate.

Acetamide when heated with phenanthraquinone in sealed tubes at 220 — 230° C., using glacial acetic acid as solvent, yields diphenanthrapiazine, an indifferent body, having a melting-point over 400° C. and belonging to the "azine" group.

78. "*The Action of Ethylenediamine on Succinic Acid.*" By ARTHUR T. MASON, Ph.D., F.I.C.

The addition compound, $C_2H_4(COOH)_2 \cdot C_2H_4(NH_2)_2$, is first produced; it crystallises in thick white prisms melting at 181 — 182° ; if it be heated above this temperature it parts with water, ethylenedisuccinimide,—

being formed which melts at 250 — 251° , and distils undecomposed at 395° . This compound gives the pyrrole reaction on distillation with zinc dust containing hydroxide. It is not attacked by bromine and water at

120°, but at 180° ethylenediamine bromhydride is formed. Ethylene disuccinamic acid,—

is prepared from the diimide by boiling with baryta-water; the acid crystallises from water in large, colourless quadratic plates melting at 184—185°; its silver salt is anhydrous; the calcium salt has the formula—

NOTICES OF BOOKS.

Dyeing: Comprising the Dyeing and Bleaching of Wool, Silk, Cotton, Flax, Hemp, China Grass, &c. By ANTONIO SANSONE. Manchester A. Heywood and Son. London: Simpkin, Marshall, and Co., and Hamilton, Adams, and Co.

THE volume before us is a worthy companion to the author's former work, "The Printing of Cotton Fabrics," and as far as the extent of 250 pages will allow, it gives a very complete and practical view of dyeing, as at present carried on in the leading seats of tinctorial industry.

The work opens with four introductory chapters. The first of these, on the "History of Dyeing," though brief, contains some interesting facts not generally known. Another chapter is allotted to the history of the coal-tar colours, from the first production of an aniline violet, down to the present day. This section concludes with an important remark:—"On the whole, it seems that the field of coal-tar colours, which has been found so rich, and given rise to so many brilliant discoveries, shows, now, signs of exhaustion (as far as really useful products are concerned), and the hopes of those who believed that all natural organic colouring-matters would be artificially produced on a large and commercial scale have, up to now, not been realised." Surely the displacement of natural colours by artificial products, whether probable or not, is not to be hoped for. Whatever tends to draw men from the open country and the fields or plantations into the cities and the factories is to be deprecated on social and sanitary grounds. It would be better to aim at methods by which the colour-yielding plants might be improved and ennobled, so as to yield tinctorial matters more abundant in quantity and better in quality. Analogous improvements are well known to have been effected in the vegetable world.

In the chapter on the characteristics of fibres we find quoted the opinion of M. Buisine that it would be remunerative to extract certain organic acids from the washings of wool. In 100 parts of the dry suint of Australian wool there were contained 7.1 acetic acid, 4 propionic, 2.6 benzoic, 2.5 lactic, and 1 caprylic acid.

In a fourth chapter Mr. Sansone proceeds to the testing of colouring-matters by dyeing. He seems entirely to reject the purely chemical methods, gravimetric or volumetric. He admits that they "may yield trustworthy results in the hands of the skilful chemist," but considers that they are not capable of general application, and are therefore seldom used in practice. It may be replied, however, that the comparative dyeing tests which the author recommends give trustworthy results only in skilful hands, as he substantially admits, and that where a previous mordanting is required, the time such tests require is an objection.

After these preliminaries we find an account of practical processes as applied to cotton, linen, jute, wool, and silk.

The topping vat blues with methyl violet is very properly pronounced a sophistication, since the effect produced is fugitive. The electrical vat, whatever development it may possibly undergo in the future, Mr. Sansone considers at present too costly and complicated to be of any real utility. From this opinion few men of experience will dissent.

Concerning jute, the author states that though the basic aniline dyes take easily on this fibre without any mordant, owing to the tannin naturally present, they fade very readily.

Under wool dyeing the author recommends the Cerrutti-Sella apparatus as advantageous for this fibre in every state in which it has to be dyed.

The basic aniline colours have lost much of their importance in wool dyeing since the introduction of the acid colours. One passage in this connection seems unintelligible from some probable clerical or typographical error. We read:—"Bismarck brown, chrysoidine, and phosphine the violets." As none of the colours here mentioned are violets the reader is left in doubt.

The dye-wood colours, as a whole, are said to have still held their own, a circumstance which we, in this country, have no reason to regret. Cochineal, however, has suffered very considerably.

We are very glad to find that the author decidedly condemns the weighting of silks as a fraud. This art "has been the cause of injuring the prosperity of the silk industry very considerably, and this beautiful fibre, which in olden time was the symbol of strength and durability, is now-a-days simply the emblem of the hollow and presumptuous show in which this age heartily delights." However, nothing but legislative interference can now avail to meet this evil.

The last portion of the book discusses new colouring-matters and a variety of miscellaneous matter.

The illustrations of this book are particularly excellent and instructive. There are forty-five plates showing the most improved machinery used in bleaching and dyeing. In the patterns illustrating different colours we notice a decided improvement. Not only are they beautifully got up, but instead of being pasted in among the text, where they get soiled, they are placed in a case, forming in fact a second volume.

Mr. Sansone deserves the thanks of all persons connected with the trade for this important addition to our tinctorial literature, and the publishers, Messrs. Heywood and Son, deserve our congratulations on the getting up of the volume.

CORRESPONDENCE.

WATERPROOFING.

To the Editor of the Chemical News.

SIR,—In answer to your correspondent, I am not aware of any article or book having been written, dealing in a special way with this subject. Spon's "Encyclopædia," article "Indiarubber," contains an article bearing on the matter generally. Hoffer's "Indiarubber," translated by Brandt, New York, contains an article on the same subject.

In treating of this matter the general principles of drying and preparing the fabric to be *proofed*, the preparation of the "dough," or proofing compound, evaporation of naphtha, &c., doubling, and curing, can be seen in operation at most factories. The only variation consists in minor details, as in any manufacturing industry.—I am, &c.,

THOMAS T. P. BRUCE WARREN.

Tamworth Villa, Earlsam Grove,
Forest Gate, E.

SULPHUR IN IRON.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS (vol. lviii., p. 177) there appeared an article by H. N. Warren on "The Dissolution of Sulphur and Phosphorus, as Observed . . ." In this

article, since FeS appears to be found after electrolysis, the theory is advanced as plausible "that the compound expressed by the formula FeS is the only combination obtainable by the simple action of sulphur on metallic iron, aided by heat, and that the sulphur does not disseminate itself throughout the whole mass of metal to form a compound possessing a formula where iron predominates largely, such as would be inferred from the formula expressed by Fe_3S_2 , and which could be arrived at by calculating from analytical data; but exists rather in the form of sulphide of iron, disseminated, so to speak, through a mass of pure iron, the sulphide present forming a simple network, allowing the current free passage; the iron, being a much superior conductor of electricity than the sulphide, becomes more rapidly dissolved, leaving the residual sulphide."

With all due respect to the writer's judgment, I cannot agree with him. In the arrangement described the FeCl_2 would be decomposed by the current, the Cl combining with the iron of the electrode, while the sulphur, if combined with the iron in any proportion, being separated in a short time, would be present on the surface of the electrode in sufficient quantity to give FeS, or even possibly FeS_2 .

So often theories are advanced without sufficient reason, that it seems to me a protest should be uttered whenever possible in such cases.—I am, &c.,

CLARENCE L. SPEYERS.

ANCIENT MORTARS.

To the Editor of the Chemical News.

SIR,—The facts enumerated by Mr. Rowland Williams (CHEMICAL NEWS, vol. lviii., p. 231) are (though not new) very interesting in their way, but can scarcely be said to throw much new light on the point raised in connection with Mr. Spiller's examination of ancient Roman mortars until a certain ambiguity, at present running through the language employed in stating those facts, is removed. To be exact, Mr. Williams must tell us the true nature of the "sand" employed in the cases he mentions. Normal clean quartzose sand is, as everybody knows, a congeries of particles of crystalline SiO_2 ; but such a sand occurs but rarely in nature; probably never, unless it has had all ferruginous or other investment of the grains removed by the leaching action of either organic acids or (in volcanic regions) mineral acids dissolved in water percolating through the deposit. Until this point, therefore, is settled, we must hesitate to draw any certain inference from the alleged facts.

Again, the geologist knows perfectly well that even clean "sands" vary in composition within rather wide limits, from a congeries of particles of rock-crystal, at one end of the series, through mixtures of SiO_2 with comminuted feldspathic, micaceous, and other silicates, to the pumiceous dust (a mixture of fragmental glassy or hydro-deitrified silicates), which constitutes normal volcanic sand at the other end of the series. Until we have precise information on these points we must "suspend judgment."

Once more, Mr. Williams makes no allowance for the many allotropic forms which SiO_2 assumes in nature. The differences in molecular structure which undoubtedly accompany such variations of the same chemical body as are exhibited (e.g.) by rock-crystal, flint, or opal, make a great difference in the readiness with which these varieties of SiO_2 (as well as silicates) lend themselves to reactions upon other substances, as has been very well shown by Rammelsberg. This point I have more fully discussed elsewhere, and herein, no doubt lies the value of the "ground flint" recommended by Messrs. Crookes, Odling, and Tidy in the case of the Huddersfield water supply. This point was brought before Section B of the

British Association at Birmingham, in 1886, by Messrs Crookes and Tidy; but one of them informed me that the removal of lead was proved to consist in the formation of silicate of lead. From the close relation in which lead stands to the bases of the alkaline earths we should expect silicate of lime to be formed under similar conditions; but are the conditions similar in the two cases?

Having been engaged a good deal in the study of reactions of this class during the past year or two, I am quite prepared to find that in the cases mentioned by Messrs. Carnelley and Frew the "sand" employed furnished a considerable proportion of feldspar or other silicates to do what Wollastonite itself was found to do; that is (probably), to furnish bases strong enough to take hold of CO_2 from carbonate of lead, and at the same time to furnish nascent SiO_2 to form silicate of lead, just as free SiO_2 in the form of a semi-vitreous colloid (as it occurs in native flint) was found to do. The effect of passing native waters through carbonate of lime (whether in the form of "old mortar" or not) is simply to apply the most commonplace fact of physical geology by giving calcareous hardness to the water; and the immunity of hard waters from lead contamination is equally well known.

How calcium silicate (Wollastonite) can aid as an antecedent to the reaction whereby lead is fixed in an insoluble form, and yet be a consequent of the reaction under the same physical conditions I fail to understand. Does not this remind one rather of such fond dreams as "perpetual motion"?

We are still confronted—as I consider—with the question as to the nature of the sand employed in the "ancient mortars," of the Roman builders.—I am, &c.,

A. IRVING.

REWARDS FOR MERITORIOUS DISCOVERIES AND INVENTIONS.

To the Editor of the Chemical News.

SIR,—The Committee on Science and the Arts of the Franklin Institute, of the State of Pennsylvania, respectfully requests that you will cause to be made known to the readers of your influential journal the fact that the Committee is empowered to award, or to recommend the award of, certain medals for meritorious discoveries and inventions, which tend to the progress of the arts and manufactures. These medals are:—

1. *The Elliott Cresson Medal (Gold).*—This medal was founded by the legacy of Elliott Cresson, of Philadelphia, and conveyed to Trustees of the Franklin Institute. By the Act of the Institution, May 17, 1849, the Committee on Science and the Arts was designated and empowered to award this medal, and the Committee decided to grant it, after proper investigation and report by sub-committee, either for some discovery in the arts and sciences, or for the invention or improvement of some useful machine, or for some new process, or combination of materials in manufactures, or for ingenuity, skill, or perfection in workmanship.

2. *The John Scott Legacy Premium and Metal (Twenty Dollars and a Medal of Copper).*—The John Scott Legacy Premium and Medal was founded, in 1816, by John Scott, a merchant of Edinburgh, Scotland, who bequeathed to the City of Philadelphia a considerable sum of money, the interest of which should be devoted to rewarding ingenious men and women who make useful inventions. The premium is not to exceed twenty dollars, and the medal is to be of copper, and inscribed "To the most deserving."

The control of the Scott Legacy Premium and Medal (by Act of 1869) was transferred to the Board of Directors of City Trusts, and referred by the Board to its Committee on Minor Trusts, and that committee resolved that it would receive favourably the name of any person whom

the Franklin Institute may from time to time report to the Committee on Minor Trusts as worthy to receive the Scott Legacy Premium and Medal.

The Franklin Institute, by resolution in 1882, accepted the above-named action of the Committee on Minor Trusts, and referred the duty of making such recommendations to the Committee on Science and the Arts. The Committee determined that the recommendation for such reward shall be made on the favourable report of a sub-committee, which shall be appointed to examine the invention or discovery.

The Committee requests your co-operation in facilitating the making of the aforesaid awards for meritorious discoveries and inventions, by bringing the facts herein set forth to the knowledge of your readers.

Upon request, therefore, from interested parties, made to the Secretary of the Franklin Institute, full information will be sent respecting the manner of making application for the investigation of inventions and discoveries; furthermore, the Committee on Science and the Arts will receive and give respectful consideration to reports upon discoveries and inventions which may be sent to it with the view of receiving one or the other of the awards herein named, and full directions as to the manner and form in which such communications should properly be made, will be sent on application.—By the Committee's order,

WM. H. WAHL, *Secretary*.

The Franklin Institute of the State of
Pennsylvania, for the Promotion of
the Mechanic Arts,
Philadelphia, Oct. 1, 1888.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 18, October 29, 1888.

The Telluric Spectrum at Elevated Stations, and in Particular the Spectrum of Oxygen.—M. Janssen.—The author ascended Mont Blanc in order to ascertain how the groups of dark lines produced by oxygen in the solar spectrum diminish in intensity with the elevation of the station, so as to elucidate the important question if these groups are entirely due to the oxygen contained in our atmosphere, or if the solar atmosphere takes a certain part in the phenomenon; in a word, if the solar light analysed before its entrance into the earth's atmosphere presents, or does not present, the bands and rays of oxygen. The author's object was merely to ascertain if the solar atmosphere contains this gas in a state in which it produces phenomena of absorption similar to those which the atmospheric oxygen occasions in light which traverses it. The groups A, B, and α of the solar spectrum have been ascribed to the presence of oxygen. They are situated in the less refrangible portion of the spectrum, in the orange and the red. But as the most important of the groups of watery vapour are found in the same region, to avoid confusion the author resolved to make his observations in very cold weather, a circumstance which, combined with the elevation of the station, would almost entirely eliminate the groups of watery vapour, and leave those due to oxygen distinct. He selected a hut situated at the Grands Mulets, on the ridge of Mont Blanc, at an elevation of 3000 metres. It was found that the rays and bands of watery vapour were entirely absent, as were also the oxygen bands in the red, the yellow, and the blue. The ray B and the neighbouring lines were much enfeebled, as was also the group α ; A was scarcely visible.

Hence the author infers that these groups would entirely disappear from the spectrum if it could be observed at the limits of the earth's atmosphere. Hence the rays and bands due to oxygen which we find in the spectrum are exclusively due to the earth's atmosphere. We are not, however, entitled to assume the absence of oxygen in the sun. We can merely say that oxygen does not exist in the sun's atmosphere in a condition capable of producing the spectral manifestations which it gives in the earth's atmosphere.

The Separation of Cobalt and Nickel by the Nitrite Method.—M. Baubigny.—The presence of lead and of the alkaline-earth metals is an obstacle to the employment of the process for separating cobalt and nickel, founded upon the action of potassium nitrite.

The Chloro-derivatives of Acetyl-acetic Ether.—M. Genvresse.—This memoir is not adapted for useful abstraction.

Bulletin de la Société Chimique de Paris.

Vol. 1., No. 3, August 5, 1888.

First Attempts at the Synthesis of Seleniuretted Organic Compounds in the Aromatic Series.—M. Camille Chabrie.—Selenium tetrachloride exerts a chlorinising action upon the aromatic carbides (benzene and toluene). Selenious anhydride and selenyl chloride react upon benzene in presence of aluminium chloride. The action of fermentation is capable of reducing selenious acid.

Contributions to the History of the Isomerism of Fumaric and Maleic Acids.—T. Ossipoff.—This memoir does not admit of useful abstraction.

Action of Phenylhydrazine and Hydroxylamine upon Acetylacetone.—A. Combes.—By the reaction of phenylhydrazine upon acetylacetone the author has obtained a liquid boiling at 270.5° at normal pressure, and presenting exactly the composition of a dimethyl-phenylpyrazol.

The Hydrochlorates of Antimony Trichloride, Bismuth Trichloride, and Antimony Pentachloride.—R. Engel.—These compounds exist, and can be obtained as well-defined salts, easily capable of isolation. All three contain crystalline water, like all the other hydrochlorates of chlorides which have been obtained. In all there are at least 2 mols. of water to each mol. of hydrochloric acid fixed by the chloride.

On the Aspartic Acids.—R. Engel.—The fixation of the elements of ammonia upon the maleic and fumaric acids yields one and the same aspartic acid, which is optically inactive, and is capable of being split up.

Thermic Formation of the Salts of the Phenylen-diamines: Researches on Paraphenylen-diamine.—Leo Vignon.—The author has undertaken to measure the quantities of heat liberated by the union of certain acids with the three phenylen-diamines. The saturation of one of the basic functions of paraphenylen-diamine diminishes the intensity of the function, which remains free. Paraphenylen-diamine is a more powerful base than aniline.

Combination-heats of the Primary, Secondary, and Tertiary Aromatic Monamines with Acids.—Leo Vignon.—From his measurements the author deduces the conclusions that the quantities of heat evolved by the successive additions of one and then two mols. of hydrochloric and acetic acid and of one and then two semimols. of sulphuric acid give the measure of the relative formation heats of the salts produced, and permit us, at the same time, to appreciate their state of dissociation under the influence of the solvent. Thus, acetic acid and aniline can unite only very imperfectly in water. The want of stability of aniline acetate shows why it has not been obtained in the solid and crystalline condition.

The Composition of Natural Brandies and the Manner of Distinguishing them.—X. Roques.—

Chemical analysis enables us to render account of the spirits in consumption. There exists a decided difference between the results yielded by natural alcohols and the artificial kinds.

Influence of the Temperature of Fermentation on the Production of the Higher Alcohols.—L. Lindet.—At low temperatures there is a less production of the higher alcohols, but to an insignificant extent.

Determination of Fluorine in Substances Decomposable by Sulphuric Acid, especially in Phosphates.—H. Laine.—This paper requires the accompanying illustration.

An Apparatus for the Preparation of Sulphuretted Hydrogen.—P. Chantemille.—This paper also cannot be usefully reproduced without the illustration.

On Cupric Chloride Hydrochlorate.—Paul Sabatier.—The author's hydrochlorate is different from that of M. Engel. The latter produced a compound answering to the formula $\text{CuCl}_2\text{HCl}_3\text{H}_2\text{O}$. The hydrochlorate of M. Sabatier is $\text{CuCl}_2\text{HCl}_5\text{H}_2\text{O}$.

Preparation of Starch Paste as Indicator in Volumetric Analyses with Iodine.—M. Gastine.—The author grinds up together 5 grms. potato-starch and 1 centigram. mercuric iodide. The whole is then stirred up in a little water, and the thin paste thus obtained is poured into a litre of boiling water. It is decanted after settling and the clear is preserved for use.

New Method for Detecting the Falsification of Pepper with Olive Kernels.—M. Gillet.—If to 1 grm. of olive-kernels we add 1 c.c. of tincture of iodine at 5 per cent the mixture takes a bright yellow colour in fifteen minutes, while the same quantity of pepper gives, with the same reagent, a brown or deep maroon. If we make up a series of type-mixtures containing 5, 10, 15, 20 per cent each of kernels, which mixtures, when once coloured, preserve their shade for years, we may easily ascertain the amount of the fraud. If the kernels exceed 20 per cent they can be seen with the naked eye.

MISCELLANEOUS.

Determination of Albumen in Urine.—Dr. H. Schauman.—The author proposes a modification of the gravimetric method for the determination of albumen in urine. Instead of the ordinary paper filter he uses a plug of cotton-wool freed from fatty matter, and pressed firmly into a glass tube drawn out to a narrow point. For this purpose a filter-tube is adapted, as introduced by Allihn for the determination of sugar. This tube, with its cotton plug, is dried at 110° and weighed. It is then fixed firmly, by means of a cork, in a filter support, which is then, in turn, connected with a filter-pump. The albumen in a weighed quantity of urine is precipitated in a beaker by the addition of a small quantity of acetic acid, and heating for half an hour on the water-bath. The clear supernatant liquid is first poured into the tube. The coagulum which adheres rather firmly to the bottom of the beaker is repeatedly washed with hot water, and the washings carefully poured upon the cotton before the precipitated albumen is introduced. This is then washed with hot water with the aid of the filter-pump, until the liquid running out no longer gives a chlorine reaction with silver nitrate. The tube is then closed at the wider end with a cork, perforated to admit a glass tube. It is then placed in a small rectangular drying box of sheet iron, provided on each of its two opposite sides with a circular aperture, into which the filter tube is inserted. The end having the perforated cork is connected with a calcium chloride tube and a washing-bottle charged with sulphuric acid, whilst the drawn-out end is connected with an aspirator. For an hour a moderately rapid stream of dried air is

drawn though the filter-tube. The temperature in the drying box is gradually raised to 100° , and, after heating to this point for an hour, it is raised further to 110° , dried air being still drawn through in a moderately strong current. After heating for two hours at 110° , the tube is weighed and re-weighed every half hour, until the weight is constant.—*Zeitschrift für Analytische Chemie*, Vol. xxvii., Part 5.

NOTES AND QUERIES.

. Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Cleansing Stone.—(Reply to J. R.).—Remove all dust with a soft brush. Then syringe carefully with rain-water (or distilled water). When dry apply a thin coating of the best Portland cement mixed with water (cement wash).—G. A. KEYWORTH, Hastings.

Waterproofing.—(Reply to Dr. Lorenz).—See short but useful article in "Cooley's Dictionary of Receipts" (Churchill, New Burlington Street, London). Large and valuable article in the "Encyclopædia Britannica" (Messrs. Black, publishers, Edinburgh, to whom apply).—G. A. KEYWORTH, Hastings.

MEETINGS FOR THE WEEK.

SATURDAY, 24th.—Physical, 3. "On the Measurement of the Luminosity of Coloured Surfaces," by Capt. Abney, F.R.S. "On the Suppressed Dimensions of Physical Quantities," by Prof. Rücker, F.R.S.

An A.I.C., who wishes to gain Experience, offers his services in a London Laboratory. Satisfactory references furnished.—Address, H., CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

A Professional Gentleman, owning the Recipe for a Valuable Medicine, wants Partner with some capital and practical knowledge to aid in developing business.—Address, "Quilibet," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Pharmaceutical Chemist, -age 23, requires Situation as Teacher, Demonstrator, or in Chemical Works. Good knowledge of Analysis of Drugs and Chemicals. Highest references as to character, &c.—Address, Hogg, Serpentine, Brixton.

Wanted, the Address of a Maker of Metallic Tungsten or Ferro-Tungsten.—Address, John H. Darby, Brymbo, Wrexham.

Wanted, Old Pyrites Burners and Fittings.—Address, "Delta," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Wanted, by Practical Man, Re-engagement as Foreman or Sub-manager in Chemical Manure Works. Having had twelve years' experience, well up in every Branch of the Manure Trade and the management of men.—Address, "Manure," CHEMICAL NEWS Office, Boy Court, Ludgate Hill, London, E.C.

Now ready, Crown 8vo., 5s.

THE ANALYST'S LABORATORY COMPANION.

By ALFRED E. JOHNSON, F.I.C., F.C.S.,
First Prizeman in Chemistry, Physics, and Mathematics of the
Royal College of Science for Ireland.

. This work will be found a handy reference book for constant use by the practical worker in nearly every branch of chemistry; and by means of the numerous factors, tables, and useful notes much time may be saved.

"The printing is clear and distinct, and the book, so far as can be seen from a perusal, seems to be very free from printer's errors. . . . There is also a very good table for calculation of phosphates specially worked out for agricultural analysts."—*Analyst*.

"That part of the book devoted to 'Weights and Measures' will be found extremely useful. . . . We cordially recommend the work to the notice of all chemists, as we feel convinced it will save a great deal of their valuable time."—*Chemical Trade Journal*.

London: J. and A. CHURCHILL, 11, New Burlington Street.

THE KEROSENE COMPANY, LIMITED. EMPTY PETROLEUM BARRELS.

THE KEROSENE COMPANY, LIMITED,
are the largest purchasers of EMPTY PETROLEUM BARRELS in the United Kingdom.

Empties may be delivered for our account in—

LONDON—to Atlantic Wharf, Bow Common; Western Wharf, Old Kent Road; and on the River Thames to Thames Haven Petroleum Wharf, Thames Haven. We also receive Empties at the various Railway Depots in London.

LIVERPOOL.—

BARROW-IN-FURNESS—To the order of the Petroleum Storage, Barrow-in-Furness.

We pay 1d. per Barrel more for Barrels branded with our own Brand, "LUSTRE," than for Barrels branded with American Brands, and 3d. per Barrel more than for Barrels branded with other Russian or English Brands.

LABELS.—Before sending any further Empties to us will you please apply to us for labels, which we supply free. Such labels to be affixed to each Barrel by the sender, so that the Empties may be recognised and all disputes avoided.

DEDUCTIONS FOR DAMAGES.—Broken Head 1s.; Broken Stave or Chimb 6d. If Bung-hole exceeds 2½ inches in diameter, 6d. If Taphole exceeds 1½, or if two tapholes in a Barrel, 6d. If the Glue be bad, 6d. For each Hoop off, 6d.

DISPUTES—Should any dispute arise as to the condition of the Barrels, the Wharf Cooper's return will be produced on application, and must be accepted as final and conclusive.

SPECIAL NOTICE.—As our Oil would be seriously damaged if put into Barrels that have contained Paraffin Oil, Paraffin Empties are useless to us, and we are compelled therefore to decline to receive them.

PRICE LIST SENT ON APPLICATION.

THE KEROSENE COMPANY, LIMITED, THE LARGEST IMPORTERS OF RUSSIAN PETROLEUM.

The whole of our Oil is guaranteed **SUPERFINE WHITE** at time of shipment.

F. & M. LAUTENSCHLÄGER, 24, ZIEGEL STR., BERLIN, N.

MANUFACTURERS AND CONSTRUCTORS OF CHEMICAL,
BACTERIOLOGICAL, TECHNICAL, AND MICROSCOPICAL
APPARATUS.

ANALYTICAL BALANCES from 30s. to £70.

Large stock of Beakers, Gas-Burners of newest design, Evaporating Basins, Stands for Burettes, Water-baths, Balances of best finish, Apparatus for Testing Human Food, &c., &c.

Gas Regulators for different temperatures ready filled for use. Glass Jars for anatomical preparations, all sizes, and Bacteriological Apparatus with latest improvements as speciality.

We shall be glad to give estimates for new complete laboratories.

WHOLESALE—EXPORT.

Water-Glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at **ROBERT RUMNEY'S**, Ardwick Chemical Works, Manchester.

GEORGE SCOTT and SON, Engineers, Ironfounders, and Boiler-Makers, (SINCE 1834), Manufacturers of Every Description of Chemical Plant and Machinery.

Air-Compressors for all pressures up to 3000 lbs. per sq. in.

and
VACUUM-PUMPS GIVING AN ALMOST ABSOLUTE VACUUM,
always in stock or in progress.

Special Filter-Presses, Blowing Engines, Vacuum Filters, Hydraulic Presses, &c., &c.

Telegrams, "Thirty-four, London." Telephone, No. 4390.

44 & 46, CHRISTIAN ST., LONDON, E.

THOMAS FARMER & CO., (ESTABLISHED 1778),

**DUNSTER HOUSE, MARK LANE,
LONDON,**

MANUFACTURERS OF

**PURE SULPHURIC ACID,
PURE & COMMERCIAL NITRIC ACID
PURE HYDROCHLORIC ACID.**

Wholesale Price List on application.

**WILLIAM FOX, ANALYTICAL CHEMIST,

THE CHEMICAL NEWS.

VOL. LVIII. No. 1513.

ADULTERATION OF COAL-TAR NAPHTHA.

By THOMAS T. P. BRUCE WARREN.

IN my previous communication (CHEM. NEWS, vol. lviii., p. 235) on this subject the word "low" in the second paragraph from bottom should be deleted, otherwise a wrong impression might arise. I give here a few numerical results on some ordinary commercial products to show the value of this method of testing:—

Designation of liquid.	I absorbed. Per cent.	Remarks.
Benzol, 90 per cent. . . .	1'911	
Toluol, commercial. . . .	4'046	Mean, 3'429 and 4'679 =4'054.
Naphtha, solvent	3'808	Sp. gr. 875 at 15'5° C.
„ product, 142° C. . . .	3'429	Sp. gr. 869 at 15'5° C. 68 per cent.
„ „ 160° C. . . .	4'679	Sp. gr. 870 at 15'5° C. 29 per cent.
„ „ residues	4'246	Sp. gr. 900 at 15'5° C. 3 per cent.
„ with 10% benzoline . . .	5'742	
Benzoline	20'980	Sp. gr. 750 at 15'5° C.
Paraffin oil, white	4'864	Sp. gr. 797.
Shale spirit	44'900	

The iodine absorption of the original naphtha is 3'808 per cent, the absorption calculated on the products is 3'801 per cent. The addition of 10 per cent benzoline to the same naphtha should give a calculated absorption of 5'525 per cent.

The addition of petroleum products will evidently increase the iodine absorption. The sp. gr. of the mixture with 10 per cent benzoline was 863 at 15'5° C.

I hope to take an early opportunity of supplementing this list with the products from coal-tar and petroleum.

THE CATALYSIS OF POTASSIUM CHLORATE AND MANGANESE DIOXIDE.

By H. N. WARREN, Research Analyst.

RESPECTING the action of heat upon potassium chlorate, either alone or when aided by the addition of manganese dioxide, so well known is the decomposition that to attempt a more explicit explanation than is afforded by the numerous text-books of science would present a grave difficulty. But, as regards the addition of manganese dioxide, when we enumerate the various hypothetical reasons that are assigned to its use, and the replacement of the same by such absurd bodies as sand, &c., even by those who are supposed to hold high stations in the chemical profession, it can be readily understood that their general mode of reasoning must either be of an alchymetical or of an extremely orthodox type. True, to speak definitely of such a reaction would be extremely precarious, owing chiefly to the instability of the salt under question when exposed to an elevated temperature, and also to the peculiarity of the decomposition of the same, namely, the formation of a chloride, which in its turn either vigorously attacks, by the formation of secondary reactions, or totally destroys or contaminates the would-be products.

Evidently the surmise that manganese dioxide is attended by surface action, which is referred to by several

authors, would, to any practitioner, be difficult to endorse, since the same portion, after separation by lixiviation, even to an indefinite number of times, is as active as in the first instance; but such cannot be said of surface actions in general, in which may be mentioned the case of finely-divided platinum, which speedily becomes impaired.

Although manganese dioxide is not the only substance that promotes the evolution of oxygen from potassium chlorate, yet, among those substances that are influential, all are observed to bear a similar ratio to one another; such, for instance, as cupric and plumbic oxide, an unstable sesquioxide of copper appears to exist. Oxide of copper has, therefore, a feeble affinity for oxygen, and though that affinity is not sufficiently adequate to retain the oxygen when separated from the potassium chlorate, it may undoubtedly aid in affecting its liberation. Sesquioxide of iron is also susceptible in the ferric acid of a higher but unstable stage of oxidation, and the same holds good of oxide of lead; hence their compounds facilitate the decomposition of the chlorate.

There is at present no proof of the existence of a higher oxide, either of zinc or of magnesium, and in accordance with the same, no perceptible effect is produced by the introduction of these compounds in place of manganese dioxide. This also would remove doubt why powdered glass and sand are as equally inert. It is also not improbable that during the decomposition of potassium chlorate, that minute traces of manganates may be produced, since the oxygen thus obtained is always contaminated with small quantities of free chlorine.

A somewhat striking experiment in favour of this may be performed as follows:—An intimate mixture of the two compounds is obtained and introduced into a wrought-iron tube, closed at one end, the further extremity being provided with a stop-cock or tap. The tube is now raised as rapidly as possible to a heat just below redness. Owing to the increased pressure exerted by the confined gas, the decomposition is much retarded. On a sudden liberation of the gas being allowed it naturally escapes with great violence, and invariably carries with it a large supply of chlorine gas. The contents of the tube also produce, on examination, proofs of distinct traces of free alkali.

Everton Research Laboratory,

WAVE-LENGTHS OF METALLIC SPECTRA IN THE ULTRA VIOLET.*

By JOHN TROWBRIDGE and W. C. SABINE.

(Concluded from p. 239).

Effect of Change of Temperature of Source of Light on Constancy of Position of Metallic Lines.

IN the process of the investigation we were much troubled by a slight shifting in position of the metallic lines upon the photographs. This shifting could be observed when the metallic lines were compared with a solar spectrum taken upon the same plate. The amount of this shifting in no case amounted to more than 0'1 or 0'2 of a wave-length. At first we thought it might be possible that there was a change in refrangibility of the metallic lines due to a difference in temperature of the source of light, and a long study was made of the influence of the temperature of the source of light upon its wave-length. When a metal was burned in the carbon electric light with varying strength of current no displacement could be observed between the lines of the metal photographed beneath each other upon the same sensitive plate. When the electric spark with a large battery of Leyden jars was substituted for the electric arc, and the metallic lines ob-

* Contributions from the Jefferson Physical Laboratory.

tained by the light of the spark were compared with those from the arc, occasionally a small displacement could be observed. This did not seem to arise from a change of position of the source of light, or from the heating of the slit of the spectroscope. A careful study of the iron lines showed us that the wave-length of the iron lines in the sun and those obtained from burning iron in the electric arc were the same to certainly one-hundredth of a wave-length. The displacement we observed was noticed only when the electric spark was employed. This shifting did not arise from a change of position of the spark in our apparatus, for it could not be produced at will by changing the position of the source of light. Moreover, when the arc light was placed in the same position that the spark occupied, no displacement could be observed in photographs taken by the aid of the arc. We were forced to conclude that through the range of temperature afforded by the electric arc and the electric spark, the wave-lengths of the metallic lines were constant. The displacement we observed was therefore referred to a jarring of the apparatus due to the noise of the electric spark. When the camera was at a considerable distance from the slit of the spectroscope, the displacement was diminished, and sometimes entirely disappeared. The entire apparatus was very solid, and the camera was clamped to a massive girder. It was difficult, therefore, to believe that the displacement could arise from the noise of the spark. We believe, however, that it can be ascribed to this cause, and that the wave-lengths of metallic lines produced by burning metals in the electric arc or by vaporisation in the electric spark, are to one-hundredth of a wave-length the same as those of the corresponding lines in the sun.

Results.

In the following table we have adopted the same symbols and letters to designate the character of the lines which the Committee of the British Association have employed. Column 1 refers to the intensity on a scale of 10. Column 2 gives our measures of the wave-lengths of the copper lines in the ultra violet from wave-length 2369.9 to 1944.1. Column 3 contains the measures of these lines by Hartley and Adeney. Column 4 are the corrections to be applied to Hartley and Adeney's results. Column 5 contains measurements by Liveing and Dewar. Column 6, corrections to be applied to their results. Column 7 gives the symbols adopted by the Committee of the British Association, which serve to describe the character of the line.

Conclusions.

It will be observed that the corrections to be applied to the wave-lengths obtained by Liveing and Dewar are progressive in their nature when compared with those which must be applied to the results of Hartley and Adeney. The difficulty in identifying lines and determining coincidences by employing the tables of metallic spectra in the ultra violet, published by the British Association, is illustrated by our work; for certain lines measured by Liveing and Dewar, which are identified by

the committee with lines given by Hartley and Adeney, are in reality removed from each other, one or two lines intervening. In certain cases the lines of Liveing and Dewar are wholly beyond identification with those given by Hartley and Adeney.

The results of our inquiry into the accuracy of the results of previous observers in measuring wave-lengths of metallic spectra in the ultra violet, can be summed up as follows:—

1. We believe that the method of photographing images of the slit upon the photographic plate due to Cornu in order to determine positions, leads to unavoidable errors.

2. The best method of determining wave-lengths of metallic spectra is by the use of concave gratings; for linear measurements are substituted for angular ones; underlying spectra are brought to the same focus as overlying spectra; and since a great number of lines are in focus on the same plate the conditions are the same for all, viz., breadth of slit, length of exposure, and source of light.

3. Hypotheses, in regard to coincidences of gaseous and metallic spectra, cannot be safely based upon existing measurements of spectra in the ultra violet.

4. The limit of the copper lines is extended by our investigation.—*Proceedings of the American Academy of Arts and Sciences.*

NOTE ON ERYTHROXYLON COCA GROWN IN INDIA.

By C. J. H. WARDEN, M.D., F.R.C.S.

TOWARDS the latter part of last year Mr. R. Blechynden, Junior, Secretary to the Agricultural and Horticultural Society of India, asked me to undertake the analysis of certain samples of coca leaves grown in India, and the results of my examination are embodied in the following communication, which I venture to lay before that Society in the hope that it may prove of interest to its members.

There are, perhaps, few drugs which have in recent years attracted so much attention as the alkaloid cocaine, contained in the leaves of the *Erythroxylon coca*. Hitherto the chief sources of supply have been from Peru and Bolivia, where the plant is largely cultivated, and from Brazil and the Argentine Republic. As regards the cultivation of the coca plant in India in former years, I have no information to offer, but in connection with its cultivation in Ceylon, the following note occurs in an article by Dr. H. H. Rusby in the *Therapeutic Gazette* for January, 1887; he writes—"as regards the exportation of the culture of coca, the experiment has been tried, I believe, but once. Several years since Mr. F. I. Steinart, of La Pay, shipped a small quantity of seeds *via* London to Ceylon, and during the past season, the first products were shipped to London and sold at a high price." Again, in the *Pharmaceutical Journal** it is stated, "It would appear probable that a supply of coca leaves may be looked for from Ceylon, the *Erythroxylon coca* plant having been grown in the botanic gardens there for several years past. At present it forms straggling bushes with long weak branches, which is considered to be due to it having, up to the present, been cultivated mostly in the shade. But Dr. Trimen thinks that if the plant were brought out in the open and subjected to a periodical plucking of the leaves, it would doubtless soon put on a much more compact habit. It blossoms profusely several times a year, but does not yield much seed, as most of the yellow faintly scented flowers fail to set; but the plant can be readily grown from cuttings. It is worth mentioning that in Ceylon a closely allied species, *E. monogynum*† is common in the hot dry districts. The

leaves of this species are said to be strikingly like those of *E. coca*, and they, before now, have been largely used for food by the poor in South India during famine, but it is not known whether they contain cocaine."

In 1885–6 the Agri-Horticultural Society distributed seedlings to the following tea-growing districts, and the samples of coca leaves received from these districts have formed the chief material with which I have worked:—Assam, Cachar, The Dooars, Darjeeling, Terai, and Jaunpore District.

In addition to the sources of supply indicated I have also examined samples grown at Ranchi, from seed obtained from Paris, and samples grown in the Society's gardens at Alipur.

In order to render my analytical results intelligible it will be necessary to first briefly describe the chemical properties of the constituents which have been described as being present in the leaves. In 1860 Nieman discovered the alkaloid cocaine. In 1862 Lossen isolated a second principle from the leaves, which he termed hygrin. The other principles, either present in the leaves or stated to be present, are amorphous cocaine, ecgonin, coca tannin, and a peculiar wax. Cocaine, the most important principle contained in the leaves, possesses all the properties of an alkaloid; it is crystalline, and forms crystallisable salts, of which the hydrochlorate is perhaps the most important. The alkaloid cocaine is only slightly soluble in water, but dissolves readily in alcohol or ether. The salts of cocaine, on the other hand, while soluble in water and alcohol, are practically insoluble in ether. The amount of alkaloid present in the leaves has been variously estimated at from traces to 0·8 per cent. When we come to consider hygrin and amorphous cocaine, the opinions of chemists who have worked at the subject appear to differ considerably. According to Stockman* hygrin exists in the leaves, while the so-called amorphous cocaine is merely a solution of ordinary crystalline cocaine in hygrin. Hygrin is described by Wöhler and by Lossen as a pale yellow volatile oily body, giving the ordinary reactions of alkaloids, hygroscopic, and forming hygroscopic salts, which crystallise with great difficulty. In opposition to this view regarding the nature of amorphous cocaine, the following remarks appeared in an editorial in the *Pharmaceutical Journal* for January 18th, 1887. "In reference to this subject we have recently received a letter from Dr. W. Merck, in which he states that his experience in working with cocaine does not agree with the opinion put forward by Dr. Stockman, and, as far as hygrin is concerned, he regards it as being a purely imaginary substance. When investigating the subject he considered it to be of especial importance to repeat Lossen's experiments with the view of obtaining hygrin, and ascertaining its properties and composition; but, as he states in his letter, all attempts to do so proved fruitless, and he could never obtain from coca leaves by distillation any product that could be regarded as an alkaloid. We are in a position to add that this has also been the experience of other operators, and it seems clear that, before Dr. Stockman's suggested explanation of the nature of amorphous cocaine can be accepted, the existence of hygrin must be established, and its capability of dissolving crystallisable cocaine demonstrated." In another editorial† on the coca alkaloids, the editor, referring to two contributions on the subject by Drs. Howard and Hesse, remarks that "both of them agree in confirming the fact that has already been pointed out in the *Journal* of the Association of an amorphous base with the true cocaine to which the production of local anæsthesia is referable. . . But it can scarcely be intended to dispute the existence of an amorphous base associated with cocaine in coca leaves,

coca leaves, and not in good condition. Treated in the same way as coca for extraction of alkaloid, they yielded 0·04 per cent of a principle which, however, did not possess the physiological properties of cocaine.

* *Journ. Pharm. Soc.*, April 23rd, 1887.

† *Pharm. Journ.*, July 23rd, 1887.

* July 25th, 1885.

† I examined some leaves stated to be of this species obtained by Mr. Blechynden from a local druggist. The leaves were larger than

in the crude cocaine imported from South America." Regarding the principle called ecgonine, there appears good evidence in favour of the view, that it does not exist ready formed in the leaves, but is a product of the decomposition of cocaine. The brief *resumé* I have given of the constituents of coca leaves indicates that the chemistry of the subject can hardly at present be considered as conclusive, and, as the editor of the *Pharmaceutical Journal* points out, "the increasing use of cocaine, not only as a local anæsthetic, but also for other purposes, and the very marked dissimilarity of many preparations of the alkaloid as met with in commerce, appear to require a somewhat more precise definition of its characters than has yet been given with any degree of authority. It is still an open question whether the amorphous substance, frequently associated with crystallisable cocaine and its salts, really possesses the anæsthetic property of the pure alkaloid, or if it does so, whether it does not at the same time produce other objectionable effects."

The method of assay adopted by me in my analyses of coca leaves was essentially the method recommended by Dr Squibb,* though in certain cases I varied the assay method in order to obtain control experiments. The process of assay first described by Dr. Squibb is stated to be based upon the process of manufacture, and is as follows:—

Take 50 grms. of the sample after having been powdered and passed through a sieve of 60 meshes to the linear inch, moisten the powder with an equal weight of alcohol of 92 per cent, to which has been added 1-60th of its weight of sulphuric acid, sp. gr. 1.843. Allow the moistened powder to stand in a closed vessel for three or four hours, and then pack it firmly in a cylindrical percolator. Percolate with plain alcohol until 250 c.c. of percolate have been obtained. Evaporate the percolate in a shallow broad capsule at a low temperature until it is reduced to about 10 c.c., and then add to this 20 to 50 c.c. of water applied in two or three portions, carefully washing out all that is soluble in water from the clots of chlorophyll and resinous extractive matter. Filter the solution into a flask or separating apparatus, add to it an equal volume of ether, shake vigorously, separate the solution, and add half its volume of ether, and again separate the solution. Add to the aqueous solution an equal volume of ether, and then solution of carbonate of soda in excess. Separate the ethereal portion, put it into a tared beaker, wash the watery liquid with half its volume of ether, and add this ether to that contained in the beaker, and set this in a warm place until the ether is fully evaporated off. Then pour upon the residue in the beaker 5 c.c. water, rinse it round well without a stirrer, and having poured off the water, dry the contents of the beaker, and weigh and subtract the tare. The net weight is that of the crude alkaloid with much colouring matter. On an average a deduction of 20 to 25 per cent of the weight will give a close approximation to the cocaine contained in the sample. The alkaloids are left in the beaker in small varnish-like drops on the side, and a varnish-like film at the bottom, but in half an hour or an hour of drying, the drops generally become star-shaped crystals, and the film at the bottom also crystallises, but these crystals when touched are found to be sticky, and no amount of drying that the alkaloid will stand is of any avail to dry them further. The percolation of the leaves with acidulated alcohol decomposes the natural salt of cocaine which exists in the leaves, and the alkaloid is dissolved in the alcohol as sulphate of cocaine. After removal of the alcohol by evaporation, the ether dissolves the colouring matter, &c., present in the extract, but has no solvent action on the sulphate of cocaine, because, as has already been pointed out, salts of cocaine are insoluble in ether. The subsequent addition, however, of carbonate of soda decomposes the sulphate of cocaine with separation of

cocaine, which is easily soluble in ether and is thus separated.

The method of assay I have described was subsequently modified by Dr. Squibb in several important particulars. In place of attempting to wash the alcoholic extract it is transferred to a bottle with acidulated water and agitated repeatedly with ether; in this manner all the chlorophyll and resinous extractive is separated, and from the aqueous solution the alkaloid is then separated by the addition of carbonate of soda, and repeated agitation with ether. The ethereal solution is then evaporated in a tared beaker, and the residue washed twice with 5 c.c. of distilled water, and after drying, weighed. This weight, according to Squibb, may generally be accepted as the proportion of crude alkaloid, and he states the results thus obtained appear to be a very close approximation to what the coca yields, but it does not yield as much to the manufacturing process by about 10 per cent, chiefly on account of the loss which occurs during the filtration through bone-black, and by splitting up; the bone-black being used on the manufacturing scale to free the alkaloid from traces of colour.

In all the samples of leaves examined by me I determined the percentage of moisture by exposing weighed portions over concentrated sulphuric acid in vacuo for several days. The ash was determined by igniting the amount used for estimation of moisture, at a temperature short of a red heat.

In Table No. I. I have tabulated the results obtained from the analysis of nine samples of Indian grown leaves, and for comparison I have included one analysis of a sample obtained for me by Mr. Blechynden from a local druggist's. This sample was an extremely poor one, the leaves were old and musty, and mixed with foreign leaves.

The variation in the amount of moisture present in the samples needs no special comments. As regards the ash yielded on incineration of the leaves, it was white, except in the second sample from Ranchi, in which it was of a decided reddish hue, from the presence of a marked amount of iron. Qualitatively, I was unable to determine any peculiarity about the composition of the ash; the ordinary mineral constituents of leaves were present. I thought, however, it might possibly be of interest to make quantitative determinations of certain salts, and in four samples of the leaves I determined the percentage of salts soluble and insoluble in water; the total amount of potash salts contained in that portion of the ash which was soluble in water, and the alkalinity of the soluble salts, expressed in terms of potash. In determining the amount of salts soluble in water, a weighed portion of the ash was mixed with distilled water, and a stream of carbonic acid passed through the mixture. The liquid was then evaporated to dryness and gently heated. The soluble salts were then extracted with water. A small measured volume of the solution was evaporated to dryness for estimation of dissolved salts, and this portion also served for estimation of free alkali, while the bulk of the solution was used for estimation of the total potash salts by means of platinic chloride. The results are shown in Table No. II.

Taking the total ash contents of the leaves calculated on the anhydrous leaves, and comparing the results with the percentage of alkaloid calculated in a similar manner, it would appear that in many of the samples examined the percentage of alkaloid is inversely proportional to the ash; but in the case of the sample from the Matelli tea gardens, a large percentage of ash is associated with a high percentage of alkaloid. (See Table No. III.).

The apparent effects of locality and methods of cultivation on the ash and alkaloid contents of the samples will be considered later.

In estimating the alkaloid contained in coca leaves by the process first suggested by Squibb, I found it impossible to thoroughly wash the alcoholic extract with even the maximum volume of water directed to be used, and the

modified method of assay was adopted. The crude alkaloid obtained by me was only very faintly yellowish in

colour, and was certainly not contaminated to any extent with colouring matter. But while no exception could be taken to the colour of the ethereal extract, it differed in one very marked particular from the crude alkaloid extracts described by Squibb, for in no single instance did the extract show any tendency to spontaneous crystallisation. The fact that certain samples of leaves fail to yield a crystallisable alkaloid has been noticed before, and has been attributed to the method of curing, or age of the leaves, or to the presence of amorphous alkaloid. Dr. Paul, in a paper, "Notes on Cocaine and its Salts" points to the fact that by mere evaporation of a solution of cocaine in water, the whole, or nearly the whole, of the alkaloid is converted into another substance, and he remarks that in the absence of any knowledge as to the state in which cocaine exists in coca leaves, it would be premature to offer any decided opinion, but if the alkaloid exists in the leaves in a free state, the fact of its being susceptible of decomposition by merely warming with water would point to the necessity of especial care being taken in the curing and preservation of coca leaves. Any degree of heating while the leaves are in a moist condition would probably exercise a damaging influence and determine the destruction of the alkaloid. It has been observed that there is a very great variation in the amount of cocaine to be obtained from different parcels of coca leaves; it may be well worth taking some trouble to ascertain whether this variation is not referrible to the mode of collecting and drying the leaves for transport. The method of curing the samples which form the subject of this communication is given in Table No. IV.

(To be continued).

On Tin.—Leo Vignon.—Tin, which has been precipitated by means of zinc from neutral solutions of stannous and stannic chlorides, is very readily oxidised. If exposed to the air for three or four days, it contains a quantity of hydrated stannous oxide, equal to the fourth or third of its weight. A relatively small quantity of stannous oxide mixed with metallic tin renders it infusible. If tin partially oxidised is heated in contact with the air, it burns without fusing. In a current of an inert gas globules of tin form and remain isolated without coalescing into a regulus. This phenomenon is analogous to that presented by mercury, which remains subdivided in presence of certain impurities.—*Comp. Rend.*, No. 19.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING OCTOBER 31ST, 1888.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolis Water Act, 1871.

London, November 6th, 1888.

SIR,—We submit herewith the results of our analyses of the 189 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from October 1st to October 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

The high quality of the water referred to in September's report has been well maintained during the past month. Moreover, the analysis of the daily samples are marked by great uniformity of excellence. Thus of the Thames-derived waters only 4 out of 130 samples examined by the oxygen process required more than 0.045 grain of oxygen per gallon to oxidise the organic matter, the average of the whole 130 samples being a little over 0.03 grain per gallon.

Of the 189 samples examined, 187 were clear, bright, and well filtered.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.

WILLIAM ODLING.

C. MEYMOTT TIDY.

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

November 10, 1888.

Prof. REINOLD, President, in the chair.

The following communications were read:—

"On the Calculation of the Coefficient of Mutual Induction of a Helix and Coaxial Circle." By Prof. J. V. JONES.

In arranging some experiments for determining resistance absolutely by Lorenz's method, the author had occasion to consider what form of standard coil was most suitable for accurate calculation, and chose a helix of large diameter with a single layer of wire. To obtain a sufficient number of turns, requires considerable axial length; and Lord Rayleigh's approximate method of calculating the coefficient was found to be insufficient where an accuracy of 100-per cent is required.

A method of calculation is given considering the wire as a helix whose equations are— $y' = A \cos \theta'$, $z' = A \sin \theta'$,

and $x' = k \theta$; those of the circle being $y = a \cos \theta$ and $z = a \sin \theta$.

The general expression for M, viz.—

$$\iint \frac{\cos \epsilon}{r} ds ds',$$

when applied to this case becomes—

$$\int_0^{2\pi} \int_0^{\frac{\pi}{2}} \frac{Aa \cos(\theta - \theta') d\theta d\theta'}{\sqrt{A^2 + a^2 - 2Aa \cos(\theta - \theta') + k^2 \theta'^2}}$$

One integration is performed by change of variables, making $\theta - \theta' = \phi'$ and $\theta' = \phi$. When θ is an integral multiple of π (say n) the integral is expressible in terms of a series involving the complete elliptic integrals E and F of modulus—

$$c = \frac{2\sqrt{Aa}}{A+a}$$

the expression for M being—

$$M = 4n\pi \frac{Aa}{A+a} \Sigma (-1)^m \frac{1.3 \dots 2m-1}{2.4 \dots 2m} \frac{1}{2m+1} \left(\frac{x}{A+a} \right)^{2m} P_m,$$

$$\text{where } x = kn\pi \text{ and } P_m = \int_0^{\frac{\pi}{2}} \frac{\cos 2\theta d\theta}{(1-c^2 \sin^2 \theta)^{\frac{2m+1}{2}}}$$

If—

$$Q_m = \int_0^{\frac{\pi}{2}} \frac{d\theta}{(1-c^2 \sin^2 \theta)^{\frac{2m+1}{2}}}$$

then—

$$P_m = \left(1 - \frac{2}{c^2}\right) Q_m + \frac{2}{c^2} Q_{m-1} \dots (B).$$

$$\text{and } Q_m = Q_{m-1} + \frac{c}{2m-1} \frac{d}{dc} Q_{m-1} \dots (C).$$

Observing that $Q_0 = F(c)$ and $Q_{-1} = E(c)$, P_1 , P_2 , &c., may be expressed in terms of $E(c)$, $F(c)$ and c .

Instead of calculating each term P_m independently, it is found easier in practice to deduce successive values from equations (B) and (C), combined with $(1-c^2) Q_1 = E$ and its derivatives. Applying the formula to a circle of 10 inches diameter, placed concentric with a helix of 20 inches diameter and 4 inches long, the value obtained is $M = n. 53.259$, whereas Lord Rayleigh's formula gives $n. 53.317$.

Prof. PERRY asked if the thickness of the wire had been considered, and whether the author could give any information as to practical working formulæ for the mutual induction between two ordinary cylindrical coils in any position.

Dr. FLEMING described a wooden anchor ring wound like a gramme armature, and having a secondary coil added, which he had devised as a standard of mutual induction, and used for determining capacity absolutely.

In reply the author said he had not considered the wire to have thickness, as he felt sure this would not affect the result for his coil by one part in 100,000. With respect to Dr. Fleming's anchor ring, he considered the difficulty of winding it sufficiently uniformly, to be a great drawback to its general adoption.

"On the Upper Limit of Refraction in Selenium and Bromine." By Rev. T. PELHAM DALE, M.A.; read by Mr. BAILY.

In a former paper (read Feb. 11, 1888) the author showed that an upper limit of refraction for selenium should theoretically exist about the middle of the visible spectrum, and the present communication describes some experiments which tend to confirm the prediction. On placing a thin film of selenium under a spectro-microscope, it was found to be opaque to rays above the

green, and previous calculation had given 5395·7 as the limiting wave-length transmissible.

Sulphur, at ordinary temperature, should have its upper limit beyond the visible spectrum, but theory indicates that increased temperature will lower the limit. It is well known that sulphur darkens when heated, and when a film of boiling sulphur was examined under the spectro-microscope, all but the red end of the spectrum was absorbed. On cooling, the region of absorption gradually retreated towards the violet end.

Selenium is also found to become more transparent as it is cooled, and its refractive equivalent is equal to that of sulphur, multiplied by the ratio of its chemical equivalent to its density. Important optical as well as chemical relations thus exist between the two elements.

The results obtained by bromine films were remarkably similar to those of selenium, the violet rays being entirely cut off.

A method of solving the equation $a \sin \theta = \sin m \theta$ (on the limiting solution of which the upper limit of refraction depends) by a table of Eulerian integrals, is given in the paper, and an analogy between total reflection and the upper limit of refraction is traced.

"Experiments on Glass in Polarised Light." By Prof. S. P. THOMPSON, D.Sc.

Irregular pieces of glass can be tested for internal strain by immersing them in a liquid of equal refractive power. Various specimens of tubing, rod, and thermometer tubes were examined in this way, all of which showed defective annealing. One piece of ordinary rod bent zigzag produced remarkable effects when rotated in the liquid. Prince Rupert's drops, a glass wedge, and a model of the "Regency Diamond" showed vivid colours, and the stems of broken incandescent lamps exhibited various degrees of annealing.

Mr. HILGER wished to know whether paralalled plates had been tested, and with what result; for he had always found pieces of shapes approaching to roundness to show greater defects than parallel plates. For this reason he always cut his prisms and lenses from rectangular blocks.

Mr. BLAKESLEY said that no perfectly annealed thermometer had been shown, and he was anxious to know whether any existed.

Mr. WILSON expressed a doubt as to whether it was possible to anneal anything, so as to be perfectly free from internal strain, and thought the act of breaking rods and tubes necessarily introduces strains.

Prof. RÜCKER asked whether the usual method of detaching a mercury column for calibrating thermometers produced any injurious effect, but the author was unable to speak decisively on the subject.

In answer to the President, Dr. THOMPSON said the liquid used was a mixture of carbon bisulphide and alcohol. His experience with parallel plates coincided with that of Mr. Hilger. As an example of the remarkable effects which could be produced on glass by various methods of cooling he directed attention to the fact that Prof. Exner, of Vienna, had produced lenses having plane faces.

"On a New Form of Standard Resistance Coil." By Dr. J. A. FLEMING, M.A.

Considerable difficulty has been experienced with coils of the ordinary B.A. construction when immersed in water or melting ice, due to leakage across the paraffin-wax can, caused by condensation of moisture. To overcome this, various forms have been tried, and the best yet yet devised is made by winding the coil in the space between two shallow annular casings, screwed together by projecting flanges. The joint is formed by indiarubber, and can be tested for leakage by immersing in water and applying air pressure through a small testing tube. The rising part of the terminal rods are enclosed in long brass tubes soldered to the upper casing, and are insulated by air, excepting at the top and bottom, where ebonite rings are placed. The top ring forms a corrugated cap, and an annular channel in its upper surface serves as a fluid insulator. The wire, which is triple silk covered, is baked

for some hours at a temperature above 100° C., and then soaked in anhydrous paraffin-wax containing about three per cent of resin.

NOTICES OF BOOKS.

Laboratory Manual of General Chemistry: Including Directions for Performing One Hundred of the More Important Experiments in General Chemistry and Metal Analysis, with Blanks and a Model for the same, Laboratory Rules and Suggestions, and Tables of Elements, Compounds, Solutions, Apparatus, and Chemicals. Prepared for Use with any Text-book of Chemistry, specially adapted to accompany "Introduction to Chemical Science." By R. P. WILLIAMS, A.M. Boston: Ginn and Co.

THE author of this book, without aiming at conciseness, is scarcely master of the art of expressing himself clearly in the fewest possible words. Thus, in the "Rules and Suggestions for the Laboratory," he writes:—"Never put down a stopper when using a reagent bottle, but hold it between the first and second fingers, and replace it as soon as you are through using it." How much more simple would it have been to say, instead of the eight words we have italicised, "when done with"!

The 10th rule does not seem intelligible. It reads:—"Pour only liquids or fine powders into the bowls, always opening the jet at first to let the water run." No "bowls" or "jets" have been mentioned as among the apparatus required. In one of the experiments the student is told to "touch a drop of the filtrate to the tongue." Here space would have been saved by writing "taste a drop of the filtrate." Speaking of sulphurous acid, we find the direction "cautiously take the odour." Why not "smell cautiously?" These defects may seem trifling, but when an author in pursuit of brevity uses symbols and abbreviations to an unpleasant extent, it seems strange that he should not use the most concise expressions consistent with clearness.

The experiments, for the most part, are well selected, and the rules for their performance are generally judicious. We can scarcely say as much for the 1st, 2nd, and 3rd experiments, relating to length, volume, and weight. The power of guessing linear dimensions correctly is of much more use to the physicist than to the chemist. Making a drawing of a glass measure, or, as the author calls it, a "graduate," and of a cube 1 c.m. on a side, are also curious laboratory experiments. Instructions in the art of weighing are very essential for the student. But, instead of attending to the most needful points, he is told, e.g., to see if 1 grm. (of salt) can be piled on a one-cent coin, to experiment with 5 grms. in like manner, and lastly to make drawings of 1, 5, and 10 grm. weights.

The Metallurgy of Gold: A Practical Treatise on the Metallurgical Treatment of Gold-bearing Ores, including the Processes of Concentration and Chlorination, and the Assaying, Melting, and Refining of Gold. By M. EISSLER, Mining Engineer and Metallurgical Chemist. Formerly Assistant Assayer of the U.S. Mint, San Francisco. London: Crosby Lockwood and Son.

THE author opens his subject with an account of the mining operations in California after the exhaustion of the placer diggings and the introduction of quartz-crushing. The method first adopted was simple and inefficient. The quartz was taken out of the mine, pulverised, and the gold extracted by amalgamation on copper plates. Much of the gold hereby went to waste, being washed away. As the lodes were worked to a greater depth the difficulties increased, as the gold

diffused through the quartz was no longer in a "free" state, but entangled. The ores capable of treatment by amalgamation alone are generally contained in that portion of a gold-bearing lode which lies above the water-line. From such portions the rebellious elements have been oxidised and leached out by the alternating action of air and water, leaving the gold free and clean. Below the water-line the gold is entangled in sulphurets incapable of successful amalgamation. The method at present in use for such material involves concentration for the removal of the useless matter, the amalgamation of the free gold, and the extraction of the rest by chlorination.

There is still, however, much room for improvement. The author informs us that not more than half the gold in the quartz is secured. The actual loss, alike in California and Australia, is at least 40 per cent. One of the oldest and best authorities in California states that in his operations gold has been taken up so fine that in distilled water at rest it would not subside in less than from five to ten minutes. In an actual average of seven years' work in Colorado, the assay value of the ore was £7 18s. per ton, while the average value per ton extracted was only about £3.

The total gold production of the State of California since 1848 has been above £250,000,000, but it is estimated that a still larger quantity has been wasted in milling and hydraulic mining. According to the researches of Dumas, gold exists in iron and copper pyrites partly as a double sulphide. The occurrence of gold in limestone has been recorded only once.

After describing at great length the operations of milling and amalgamation, and pointing out the conditions, the author refers to the observations and experiments of Prof. Skeay as throwing a light upon the difficulty experienced in extracting gold by amalgamation. Sulphuretted hydrogen renders gold non-amalgamable. Hence Skeay concludes that the natural surfaces of native gold are covered with a thin film of gold sulphide.

The process of chlorination, with all the necessary appliances, are described in full with the aid of the necessary illustrations.

The two remaining chapters discuss the melting, refining, and assaying of gold, and the chemical examination of gold ores.

We can strongly recommend this work to all persons who are directly or indirectly interested in gold-mining and its kindred operations.

Handy Book of Medicine Stamp Duty, with the Statutes and Appendices. By E. N. ALPE, of the Middle Temple and the Inland Revenue Department, Somerset House. London: Offices of the *Chemist and Druggist*.

If it be true, as we doubt not, that the intellectual education of any nation or any class is inversely as the demand for patent, quack, or "proprietary" medicines, Britain has little to boast of, and further, we do not seem to be improving. The work before us probably owes its existence to recent misunderstandings which occur between pharmacutists and the Inland Revenue Department. The former complain that the law and the practice on this subject are obscure, and admit sometimes of arbitrary interpretation. The Revenue officials seem to think, on the contrary, that the rules governing the administration of this branch of the law are very simple and comprehensible. Hence the publication of this book should do good service.

The subject, however, is eminently unpleasant. The fulsome advertisements which we encounter on the walls, in public conveyances, and in the press—especially in religious journals—are a painful proof of public gullibility. How is it that our Chancellors of the Exchequer do not levy a heavier contribution upon a business at once so lucrative and so inimical to the public well-being? A list is given of the persons who hold or have held patents for

quack medicines. It is worthy of note that some of the most diligent advertisers do not figure in the list.

Chemical Laboratory Labels. Compiled by H. H. SYMONS, F.R.M.S., F.C.S., F.I.C., &c. Idris and Co., Kentish Town.

THESE labels are printed in a good bold type, and the eye is not distracted by the presence of formulæ and molecular weights. For those who want such data to appear on their reagent labels, they are printed separately and may be subjoined. The names adopted will, to many chemists, have an unfamiliar sound. The acids have disappeared, and have become hydrogen chloride, hydrogen bromide, &c.

Handbook of Sydney for the Use of the Members of the Australian Association for the Advancement of Science. Edited by W. M. HAMLET, F.I.C., F.C.S., Government Analyst. Sydney Meeting, 1888. Sydney: Turner and Henderson.

THIS little handbook contains, besides an introduction from the pen of the editor, chapters on the climate, by the Government Astronomer, H. C. Russell, F.R.S.; on the geology of the district, by C. S. Wilkinson, F.G.S.; on the local botany, by J. H. Maiden, F.L.S., of the Technological Museum; an account of the mammals, by Dr. G. Bennett, F.Z.S.; the marine fauna, by Dr. W. A. Haswell, F.L.S., of the University of Sydney; the insects, by A. Sydney Oliff, F.E.S., of the Australian Museum; the mollusks, by Dr. J. C. Cox, F.L.S.; commerce and industries, by C. Lyne; and an itinerary, by the editor.

The birds and fishes, or rather the sections describing them, have, the editor informs us, disappeared without any fault of his own.

The mean annual temperature, as Prof. Russell informs us, is only 62° 6', which does not exceed the mean of Toulon and Barcelona. But while Barcelona has a summer temperature of 76° 1', and Toulon of 75° 2, that of Sydney is only 71° 1'. In return, the winter temperature of Sydney is 54°, against 50° at Barcelona and 48° 5 at Toulon.

The list of excursions is tempting in its variety. One of those suggested is a trip to the Sydney Sewage Farm at Shea's Creek. It is scarcely needful to say that in the dry climate of Australia sewage-irrigation must be very much more appropriate than in Britain.

The Annual Report of the Public Analyst appointed for the Parish of St. George, Hanover Square, upon the Articles Analysed during the Year ended March 25, 1888.

By CHARLES E. CASSAL, F.I.C., F.C.S., Public Analyst. THE articles which have been analysed include 47 samples of dairy produce, 36 of condiments, 32 of cereals and farinaceous matters, 24 of tea and coffee, and 12 of sugar, forming a total of 151. Of these, 116 were genuine, 21 adulterated, and 14 of inferior quality, but which could not be decisively called adulterated. On comparing these results with those obtained in the previous year, 1886-87, we see a distinct improvement, the genuine samples having risen from 61·9 to 76·82 per cent, the adulterated falling from 20·4 to 13·91 per cent, and the inferior from 17·7 to 8·61.

The samples of milk, if taken separately, show an improvement. The "genuine" samples have increased from 20·8 to 47·06 per cent, the adulterated simultaneously decreasing from 58·4 to 29·41 per cent. The inferior samples, however, remain substantially at the same point, being 20·59 per cent as against 20·8 per cent in the previous season. Mr. Cassal also remarks that many of the samples which had to be regarded as genuine were by no means of the best quality. It seems evident that milk-dealers are learning how to keep within the letter of the

law, and skim or water their milks down to the limit of safety. Legal proceedings were taken in seven cases. One of the offenders escaped under the plea of "warranty." The fines inflicted in the other six cases amounted only to a total of £8 ros., or less than 30s. each, a sum quite insufficient to deter from future dishonesty.

The Annual Report of the Public Analyst Appointed for the Parish of Kensington upon the Articles Analysed during the Year ended 31st March, 1888. By CHARLES E. CASSAL, F.I.C., F.C.S., Public Analyst.

DURING the year in question 503 samples have been submitted for analysis by the Inspectors under the Act. Of these 229, or nearly one-half, were milk, 47 butter, and 28 coffee. On comparing the year's results with those of the two former years, we find the articles pronounced genuine rising progressively from 48.7 to 53.0 and 72.2. The adulterated samples have fallen from 34.5 to 28.0, and finally to 15.3 per cent. The "inferior" articles, on the contrary, show no such improvement. In 1885-86 they were 11.1 per cent, in 1886-87 17 per cent, and in 1887-88 again 11.1 per cent.

Milk was, as usual, the worst article. Of the 229 samples examined 62 were adulterated, in many instances grossly so, in addition to 33 pronounced inferior and 7 abnormal. Even here, however, there is steady improvement. The samples of milk other than genuine and normal amounted in 1885-86 to 71.0 per cent, in 1886-87 to 62.14 per cent, and in 1887-88 only to 44.54 per cent. Small amounts of boracic acid were detected in seven samples, and not a few of the samples are rightfully pronounced "dirty," containing mineral and vegetable débris and epithelial scales.

Coffee still retains that bad position which it owes to the late Sir C. Wood, who, from whatever motive, when Chancellor of the Exchequer, first legalised the sale of chicory in admixture with coffee. It is much to be regretted that the Sale of Food and Drugs Act still allows highly chicorised mixtures to be sold without the usual label under the mendacious names "Coffee as in France," &c.

Mr. Cassal calls attention to a defect in the "Margarine Act." Salt or other preservative and colouring matter may be added without any limitation either as to their quantity or quality.

It is to be further regretted that magistrates not uncommonly grant applications for adjournment in case of perishable articles. It is very desirable that the importation and sale of substances used for adulteration and not having any legitimate application should be interdicted. As an instance we may mention olive stones, whole or ground.

CORRESPONDENCE.

WARNING TO CHEMISTS.

To the Editor of the Chemical News.

SIR,—Shortly after the appearance of your letters of warning, published on the 13th and 20th of January last (CHEM. NEWS, vol. lvii., pp. 23 and 30), I had an opportunity of seeing the German impostor therein described. Between then and now many of my friends have been victimised, but not yet myself. Some of us are familiar with his personal appearance from the fact of his not keeping a good account of the places or persons upon whom he has called, and we notice that he is continually changing his name, sometimes even two or three times a day. Just lately he is again busy at his tricks, having netted several pounds from unsuspecting sympathisers of my acquaintance in London, who were ready to help him on his way back to Germany, where he never goes.

Another tale is that he is awaiting remittances from his own country to enable him to proceed to Huddersfield, where he has promise of an appointment; but as he repeats the self-same story at long intervals of time, the fact of imposture is perfectly clear. His last and latest scheme is to approach the London members of the Zurich and German Chemical Societies, producing the printed lists of membership to help his enquiries, and telling off one chemist against another as having aided him in his (temporary) difficulties.

Your second writer, "Analyst, F.I.C., &c.," says he began his tricks in Scotland in the summer of 1887, and concludes his letter by expressing "the hope that this correspondence will warn others, and enable them to hand him over to the police." This may now be done, for there is a Bow Street warrant out against him. Fifteen months is a long time for a suffering profession to put up with the barefaced rascality of this young Teuton. Age about 27, height 5 ft. 9 in., slim figure, slight moustache, no beard; hair rather dark and parted near the middle; wart on forehead, above the left eye; for breast-pin he sometimes wears a cheap imitation of a 20-mark piece. He claims to be a Ph.D.; speaks English with a decidedly German accent; respectable in appearance, with black cloth overcoat and round-shaped felt hat. Generally a chemist, but has been known to pose as an engineer.—I am, &c.,

ANOTHER F.I.C.

London, November 19, 1888.

SULPHUR IN IRON.

To the Editor of the Chemical News.

SIR,—In reply to Mr. L. Speyer's criticism on my note entitled "The Dissolution of Sulphur and Phosphorus" (CHEM. NEWS, vol. lviii., p. 177), I would state, in the first place, that Mr. Speyers is evidently unfamiliar with electro-dissolution, and at once condemns it, as he states, as being plausible, although he does not even state whether he has ever performed such an experiment. Secondly, his statement with respect to the liberation of sulphur is incorrect. It is true that by acting on a saturated sulphide, by the aid of a powerful electric current, sulphur may be liberated, but exactly a reverse action is observed when iron containing only small quantities of sulphur is operated upon.—I am, &c.,

H. N. WARREN.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 19, November 5, 1888.

The Occlusion of Gases in the Electrolysis of Copper Sulphate.—A. Soret. — The author finds that electrolytic copper always contains a certain quantity of gas, consisting almost exclusively of hydrogen. It retains a little carbonic acid and a very small quantity of carbon monoxide. There exists a certain relation between the quantities of occluded gas and the conditions of temperature and acidity at which the deposit has been obtained, conditions which are again related to the malleability of the metal. This internal gaseous atmosphere is consequently variable, and the quantity of 4.4 vols., found by Lenz, holds good for merely the particular conditions of his experiments. This number corresponds to a very brittle deposit, and is one of the highest observed. The

hydrogen is never combined with the copper, but merely occluded.

On Homo-pterocarpine and Pterocarpine obtained from Santal Wood.—P. Cazeneuve and L. Hugouenq.—The authors adopt to these two compounds the respective formulæ $C_{24}H_{24}O_6$ and $C_{20}H_{16}O_6$.

On a Body, at once Acid and Base, contained in Cod-liver Oil (Morrhucic Acid).—Arm. Gautier and L. Mourgues.—The compound in question has the composition $C_9H_{13}NO_3$, and differs from tyrosine merely by containing two more H. The acid exists in the oils in the form of a complex and unstable body, behaving like the ordinary lecithines, being decomposed if heated in presence of acids or alkalies, liberating glycerin, phosphoric acid, and a complex acid. It belongs to the pyridic series.

On Yaraque, a Fermented Drink used by the Savage Tribes of the Upper Orinoco.—V. Marcano.—The basis of this preparation is cassava. The fact of a mould whose spores act as an alcoholic ferment, though exceptional in temperate climates, appears very general under the tropics.

Study on the Analysis of Brewer's Yeast.—M. Martinand.—The quantity of maltose left untouched after six days at 25° by *Saccharomyces ellipsoideus* differs so widely from that left by *S. cerevisiæ* that these two ferments cannot be confounded.

— — —
Zeitschrift für Analytische Chemie.
Vol. xxvii., Part 5.

What is the Value of the Recent Quinine Tests? Experiments towards a Fundamental Treatment of the Question.—W. Lenz.—This voluminous treatise does not admit of abstraction.

Action of Hydrogen Sulphide upon Arsenic Acid.—Le Roy W. McCay.—If a slow current of sulphuretted hydrogen is passed into the solution of an alkaline arseniate, acidulated with sulphuric or hydrochloric acid, and heated to 70° , there is formed, along with some pentasulphide, a larger or smaller quantity of free sulphoxy-arsenic acid, which, under the influence of the strong mineral acid, is split up into arsenious acid and sulphur. The arsenious acid thus formed is immediately attacked by the sulphuretted hydrogen and thrown down as arsenic trisulphide.

Determination of Ash.—F. A. Flückiger.—The substance in question is heated so slightly in a roomy platinum or porcelain crucible that it is carbonised without flame. It is convenient to cover the capsule with a net of platinum wire. When the emission of vapours has ceased it is let cool, an abundance of water is added to the spongy carbon, and it is perfectly dried on the water-bath. When this is effected it is again heated very gently (to prevent loss), and the temperature is raised very gradually. In general the carbon smoulders away very rapidly; but if not, the treatment with water is repeated and the ignition begun again.

Determination of Albumen in Urine.—Dr. H. Schauman.—Already inserted.

Apparatus for Generating Chlorine.—A. Vosmaer.—The apparatus cannot be intelligibly described without the accompanying figure. The author states that chlorine thus obtained is free from oxygen.

Salicylic Acid for the Preservation of Standard Solutions.—Hugo Bornträger.—The author finds that a standard solution of sodium thiosulphite was preserved unchanged for six weeks by the addition of a little salicylic acid. He ascribes the decomposition of many normal solutions to micrococci in the distilled water.

The Rate of Evaporation as a Measure for Vapour-Pressure.—W. Müller-Erbach.—The editor merely

mentions this method, and refers for the details to *Annalen der Physik und Chemie* (xxxi., 1040).

Changes in the Weight of Bodies on Variation of the Hygrometric Condition of the Surrounding Space.—G. Papasogli (*L'Orosi*).—The author examines if the watery vapour which condenses on dried substances during weighing is indicated by a sensitive balance. He found that if the doors of the balance-case are kept open whilst weighing a dried substance, a perceptible increase of weight ensues. Pulverised substances, dried over sulphuric acid, take up from 1 to 3 m.grms. during the time of weighing (three to six minutes).

The Absorption of Gases by Petroleum.—St. Gniewosz and Al. Walfisz (*Z. Physik. Chemie*).—The coefficient of absorption of petroleum for oxygen and many other gases is much higher than that of water. The authors conclude that the superstratification of aqueous liquids with petroleum in order to preserve them from oxidation is illusory.

A New Form of Photometer.—W. Grosse.—A mere reference to the *Zeitschrift für Instrumentenkunde*.

Electrolytic Apparatus.—Various arrangements due to W. H. Herrick (*Journal of Analytical Chemistry*) and N. von Klobulow (*Journal für Praktische Chemie*).

A Mercury Valve in place of Glass- and Pinch-Cocks.—C. Reinhardt.—This appliance is especially for use with burettes containing stannous chloride. The lower end of the syphon tube is allowed to dip in a small cylindrical vessel of mercury. Above the level of the mercury is a lateral tube bent slightly downwards, and serving for the outflow of the liquid. The mercury vessel is suspended by means of a bayonet-point to a thickened part of the syphon, and can be lowered when the syphon begins to act.

Self-acting Apparatus for Washing Precipitates.—A. Wahl (*Chemiker Zeitung*).—A flask is closed with a stopper having three perforations, one of which admits a syphon having its opening over the filter, whilst the shorter limb reaches down to near the bottom of the flask. Through the second perforation there enters a tube for the supply of water, regulated by a screw pinch-cock. The third orifice admits a tube open at both ends for the escape of air.

The Determination of Ammonia.—Th. Schlösing.—From the *Comptes Rendus*.

The Direct Precipitation of Nickel in Presence of Iron.—Thomas Moore.—From the *CHEMICAL NEWS*.

Analysis of Nickel Silver.—Thomas Moore.—From the *CHEMICAL NEWS*.

Separation of Lead from Bismuth.—H. Hermann.—From the *Journal of Analytical Chemistry*.

Separation of Tin and Antimony.—Ad. Carnot.—From the *Comptes Rendus*.

The Soda-lime Method for the Determination of Nitrogen.—W. O. Atwater and C. D. Woods.—From the *American Chemical Journal*.

The Stalagmometer, an Instrument for Determining the Proportion of Fusel Oil in Spirits, Determination of Alcohol and Acetic Acid.—J. Traube.—This paper requires the accompanying figure.

A Further Method for the Bacteriological Examination of Air.—Dr. Percy Frankland.—From the *Philosophical Transactions*.

Determination of Dry Matter in Syrups, &c.—M. Courtonne.—The author weighs about 2 grms. of the sample into a small flask, heats the flask for a few minutes in the water-bath, and exhausts the flask with the air-pump, still heating. Desiccation is effected in thirty minutes, giving a constant result.

Detection of Methyl Alcohol in Ethylic Alcohol.—J. Habermann.—A modification of the Cazeneuve-Cotton permanganate process. In order to eliminate

from commercial alcohol or brandy certain impurities which, though not identical with methylic alcohol, have a similar reducing action, Habermann shakes up 30 to 40 c.c. of the sample with 20 c.c. of the purest olive oil in a parting-funnel. The shaking must not be violent, but protracted. It is then let stand quietly until the fatty oil has separated from the alcoholic-aqueous liquid. The oil is poured off and the alcoholic-aqueous liquid, with 20 c.c. more oil, are again put in the funnel, and the process of shaking and separation is repeated, as above, and the alcohol freed from the oil is then passed through a double filter, well wetted. The clear filtrate has no smell of an ethereal oil, and, if no sugar is present, it can be at once examined for methylic alcohol by the process of Cazeneuve and Cotton. If sugar is present it is got rid of by means of distillation, the distillate being taken for examination.

Resistance of Materials to Frost.—Ad. Blümcke.—The author places cubes of the material in question, covered with distilled water, under the bell of an air-pump. On evacuating, the pores of the material are filled with water. It is then exposed to the action of a freezing mixture in a peculiar apparatus. The smaller the weight of the particles which a cube loses after a given number of freezings, the greater is its resistance to frost.

Recognition of Sulphonal.—M. Scholvien.—Pure sulphonal melts at 125.5, dissolves in 15 parts boiling water and 500 parts water at 15°. It dissolves in 2 parts of boiling alcohol, in 133 parts alcohol, 133 parts of ether, and 110 fifty per cent alcohol, all at 15°. Besides determining the melting-point, it should be examined for sulphuric acid, potassium, and manganese.

Detection of Phenacetine in Acetanilide.—If the hydrochloric solution is diluted with 10 vols. water and a few drops of a 3 per cent solution of chromic acid are added, the liquid becomes of a ruby-red if phenacetine is present. If the acetanilide is pure the solution remains yellowish.

Direct Detection of Chloral or Chloroform in Liquids.—C. Schwarz.—If a solution of resorcline containing traces of chloral hydrate or chloroform is heated to a boil with excess of soda-lye there is formed a red colour, which disappears on acidulation and returns on the addition of an alkali. If 0.1 grm. chloral hydrate or chloroform is heated with an excess of resorcline (0.3 grm.) and very little soda-lye to a strong boil, there is produced a yellowish red liquid which, even when extremely diluted, shows a splendid yellowish green fluorescence.

The Atomic Weight of Gold.—G. Krüss, T. E. Thorpe, P. A. Laurie, and J. W. Mallet.—Krüss obtains, as the mean value, 196.64; Thorpe and Laurie give Au = 196.852 (O = 15.96), and Mallet, whose researches are not completed, considers all these figures too low.

MISCELLANEOUS.

Department of Science and Art.—Mr. W. Crookes has presented to the Department of Science and Art a collection of 68 radiometers and similar instruments for permanent exhibition in the Science Galleries of the South Kensington Museum. They illustrate the steps by which Mr. Crookes was led to the construction of the radiometer, and to the production of motion and of phosphorescence by streams of electrified molecules in high vacua. Many of the instruments are of the greatest historical interest. Among them is included the first radiometer, with many others which are described in Mr. Crookes's papers in the *Philosophical Transactions of the Royal Society*. Nearly all are in working order, and will be of great use in illustrating lectures to students in the Normal School of Science at South Kensington. The collection will be on view in the galleries of the museum

in Queen's Gate as soon as the necessary stands and fittings are completed.

Royal Institution.—The next Course of Christmas Lectures adapted to a juvenile auditory will be given by Professor Dewar, F.R.S., the subject being "Clouds and Cloudland." They will begin on December 27. During the recess the staircases leading from the gallery of the theatre have been considerably altered in order to facilitate more speedy egress.

NOTES AND QUERIES.

* * * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Glazes for Earthenware.—Can any correspondent tell me title, author, and cost of a good book on Glazes and Glazing for Earthenware, such as terra-cotta, white ware, &c.—W. J. COOPER.

Earrings.—In "The Correspondence of the Right Honourable Sir John Sinclair, Bart.," vol. ii., p. 309 (London, 1831), writing on Vienna and the state of society there in 1786, the following passage occurs:—"The dust likewise occasions complaints in the eyes; numbers of men on that account wear earrings, which they insist are good for the eyes; the hole in the ear and the weight of the earring drawing any humour in the eyes to those parts." Will any contributor, foreign or otherwise, kindly inform me whether this theory mentioned by Sinclair regarding the beneficial effect of earrings in reference to men's sight in Vienna has ever been criticised in any German chemical or medical publication of that metropolis, giving also the name of periodical and date?—MARIA TRIBUS.

MEETINGS FOR THE WEEK.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37,746,

with increased effect through abolishing the noxious spaces; best Air-Pump for Compression and Evacuation; useful effect up to 90 per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment, with Attachment for Filtration with Exclusion of Air; in Wood, Iron, or Bronze every desired size

Experimental Filter Presses

in Wood, Iron or Bronze.

Filtration Experiments, if desired, carefully conducted in our Laboratory).

Steam Pumps & Transmission Pumps, horizontal, vertical, mounted on column, Wall Pumps, Pumps for Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids. "Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids, any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof, i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c. Also Small Ice Machines for Families, Laboratories, Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure, or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Compound Steam Engines. From 2—150 horse-power]

Steam Water Pumps,

newest, most approved Construction, taking up little room, and especially suitable for placing in Wells, with great efficiency; up to largest sizes.

Compressors driven by Steam or Belt, for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon Ether, Alcohol, Acetone, Water; In Iron or Copper. (Extraction Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.

Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans, and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin Refineries, Resin Distilleries, Paraffin Works, Tar Distilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest References for our above-named Specialities on Application.

VOL. LVIII. No. 1514.

"SEALED PAPERS."

IF we read the accounts of the meetings of foreign scientific societies we find it not unfrequently stated that M. A.B. or Herr X.Y. demanded that a "sealed paper," which he had deposited with the secretary some time ago, should be opened and read. This is accordingly done, and M. A.B. or Herr X.Y. aforesaid, is sometimes, in consequence, proclaimed to have been the "first and true discoverer" of some novel fact or of some important generalisation. It not unfrequently happens that such fact or generalisation has been come upon or arrived at by some other *savant*, who, of course, has been in complete ignorance of the contents of the mysterious document, but now finds that he has been anticipated.

How this custom of depositing "sealed papers" has sprung up it is not hard to conjecture. An investigator in any science may have come upon the track of some phenomenon or some conclusion, but from lack of time, of materials, or of facilities of other kinds, he may be unable to follow up the clue which has thus come into his hands. To secure his rightful claim he therefore sends in to some society a "sealed paper" containing a sketch of his results. Should anyone else take up and work out the subject, the depositor is always thus enabled to claim priority.

Now, so far little harm is done. But, unfortunately, the system of "sealed papers" lends itself to a serious abuse, which we will endeavour to explain. In research, whether in chemistry or some other science, we often reach a point where two—or more—alternatives present themselves. Let it be the valency of one of the less known elements, the product of a certain reaction, or the constitution of a newly-discovered compound. We may be fairly certain that one of the alternatives *must* be true, but to find out which is the one may require a course of prolonged and delicate experimentation. Such experimentation the conscientious chemist cheerfully undertakes, or else frankly leaves the task to others. But, if he is more mindful of his own *kudos* than of the progress of science, and craves to reap where another has sown, he finds the sealed paper supplies him with the means. He writes down each alternative in a separate paper, seals them up, and numbers them, carefully noting down the contents of each, and then hands them in for safe keeping to the Council of some Society. Months, or perhaps years, may elapse, and the papers still slumber in their pigeon-holes, their contents known to no man save the depositor. One day a memoir is read before some other society, or appears in some other journal, fully and finally solving the question at issue, and its author obtains due credit. But now steps forward the depositor, and requests that "sealed paper" No. 2, deposited on such a date, be opened and read. In this paper our hero is found to have anticipated the result which has just been given to the world, and goes off in triumph. True, his announcement may be couched in language more oracular than explicit. True, also, that his co-discoverer has worked in perfect independence. Still, the depositor obtains credit which is not justly his. As for the other sealed papers, which had been prepared in case some other alternative had been demonstrated, they may remain for ages in the desk of M. le Secrétaire. Indeed, we believe that in some cases the depositor may have them destroyed unopened.

Now, there is a method in common use, both in Britain and in Germany, which answers every good end of the sealed paper, without lending itself to the above-

mentioned abuse. The *savant* who thus comes upon some novel phenomenon, which he has not time to work out in detail, simply reads a preliminary notice, and adds that he either reserves the further investigation of the subject to himself, or, that his time, &c., not permitting him, he hands it over to his colleagues. By this plan all rights are secured and no wrongs are facilitated.

As we hear of attempts made to introduce the "sealed paper" system into this country, we shall be happy to hear the views of our readers on the question.

THE SENSIBILITY OF EARTH-NUT OIL TO HEAT WHEN ELECTRIFIED.

By THOMAS T. P. BRUCE WARREN.

WHEN working on the electrical resistances of the fixed oils, a short time ago, I found that earth-nut oil (*Arachis hypogea*), when electrified, became so extremely sensitive to heat, that every precaution was necessary to avoid changes of temperature when testing.

The apparatus used was designed for measuring the resistance corresponding to unit volume.

Two fixed parallel silver plates, insulated from each other, were placed in a test-tube, and the oil afterwards poured in. The galvanometer deflection was noted in the usual way, the tube being slightly held between the fingers. The deflection *increased*, whereas the same oil, tested in the cylindrical form of apparatus, gave a deflection which *decreased* on prolonged contact with the battery. The difference could only be accounted for by the warmth of the fingers reducing the resistance.

The tube was then wrapped with several layers of cartridge paper, and held in a cork fitting into an ordinary hydrometer glass, the annular space between the two glasses was filled in with layers of paper, coiled round the tube. The whole arrangement was allowed to stand in the neighbourhood of the galvanometer for twenty to twenty-four hours before testing. The behaviour of the oil now was similar to what it had been when tested in the cylindrical form of apparatus.

The following experiments were made with a view of ascertaining how far the warmth of the fingers had contributed to the previous result. On slightly touching the outer glass the deflection rose, and continued rising as long as the glass was touched; on claspings the outer glass the deflection increased rapidly, and, curiously, the deflected position was permanent on removal of the hands. Experiments were made to ascertain if these effects were, in any way, due to induction, with negative results. A lighted wax vesta was held about twelve inches from the cylinder, with the same result which was found by claspings with the hands, though in a less degree.

To realise the significance of these results, it is important to bear in mind that the annular space between the two glasses was nearly half an inch, and this was well filled in with a medium impervious to the rapid transmission of heat. In this case the outer glass, touched slightly with the finger, showed the same instantaneous result.

Even the very best solid conductors, such as copper or silver, do not show this remarkable behaviour to heat. It is no exaggeration to say that a mere fraction of a degree of temperature is rendered instantly visible.

An important and interesting question opens up, whether electrification increases the susceptibility of bodies to heat? At any rate, no other oil behaves in so pronounced a manner, but a mixture containing earth-nut oil shows this susceptibility in a degree proportional to the quantity present.

A few practical applications may arise from this, notably the construction of an electrical thermometer, when we consider the time required for heat to permeate a thin layer of indiarubber, gutta-percha, varnishes, &c.

THE FORMATION OF OXYGEN FROM MANGANESE PEROXIDE AND POTASSIUM CHLORATE.

By V. H. VELEY.

As regards the communication of Mr. H. N. Warren (CHEMICAL NEWS, vol. lviii., p. 247), I would wish to point out that in a recent paper "On the Conditions of the Evolution of Gases from Liquids" (*Phil. Trans.*, 1888 (1), 271), I have shown that substances, in their nature chemically inert, promote the evolution of oxygen from potassium chlorate. Thus, in a comparative experiment, into the details of which it is not necessary to enter, it was ascertained that the presence of as small a quantity as one per cent of precipitated barium sulphate in the potassium chlorate caused an increase in the rate of evolution of oxygen from the salt. Further, it was noted that, whereas oxygen was given off from a mixture of potassium chlorate and manganese peroxide at a temperature below the point of fusion of the salt, yet, under the same conditions, little or no gas was given off from a similar mixture of potassium chlorate and barium sulphate. Thus the two phenomena differ in degree; doubtless they result from different causes. The former is in accordance with other observations by Mr. Vernon Harcourt and myself on the effect of finely-divided particles in promoting the evolution of gases from liquids. As regards the latter, the effect is the result of mixed causes, viz., the finely-divided state of the manganese peroxide, and the chemical interaction between it and potassium chlorate.

It is generally stated in the text-books that the efficiency of manganese peroxide is due to the alternate formation and decomposition of potassium manganate. But this view has not, so far as I am aware, been supported by any experimental evidence. It would appear more probable that the comparatively unstable manganese dioxide, viz., the substance represented by the chemical symbol MnO_2 , is alternately formed and decomposed. The experiments of Mr. Pickering and myself (*Journal of the Chemical Society*, 1879, 659; and 1880, 585) have established that manganese peroxides, containing a proportion of oxygen less than that required for the atomic ratio $Mn : O_2$, absorb oxygen, when heated to 160° to 200° , and yield it up again at a higher temperature. This alternate absorption and evolution of oxygen under the conditions of temperature required may account for the peculiar effect of manganese peroxide. The efficiency of litharge may equally be due to the alternate formation and decomposition of the dioxide.

It would be interesting to compare the relative effects of the various metallic oxides stated by the text-books to be efficient, as also to confirm the statement that these oxides are unaltered at the end of the reaction. We are even now in the dark as to the explanation of this chemical change, which is generally the first presented to a beginner in the study of chemistry.

NOTE ON ERYTHROXYLON COCA GROWN IN INDIA.

By C. J. H. WARDEN, M.D., F.R.C.S.

(Continued from p. 251.)

IN addition to the samples, the composition of which I have given in Table No. I., I also examined two lots of leaves grown at Amgoorie, Assam; one sample, which I shall designate A, was treated like the tea leaf and allowed to ferment one hour after rolling, before it was dried; the other sample, B, was dried at once after rolling.

	Moisture.	Ash.	Alkaloid.
A sample	4'36	9'83	0'419
B "	6'47	—	0'445

The character of the ethereal extract yielded by these samples differed in no wise from the extracts yielded by samples of leaves which had been dried by simple exposure to heat. In both the samples the ethereal extract possessed in a marked degree the physiological action of cocaine when applied to the tongue.

In order to determine whether or not the process of assay I had adopted was a cause of the non-crystalline character of the alkaloid, I tried a variety of experiments. In Squibb's process heat is employed to evaporate the alcoholic extract of the leaves, and the fluid is always strongly acid in reaction: to render the alcoholic solution as free from acid as possible, I added oxide of magnesia before evaporation. The extracts, however, obtained did not differ from those yielded by the ordinary process. I may mention here that in all my estimations a very low temperature was used for driving off the alcohol. The water in the water-bath being kept at from 70° to 80° C., and the capsule containing the liquid not being in contact with the steam, but merely placed on the closed metal top of the bath. But low as this temperature was, in some experiments I avoided the use of heat altogether in the extraction of the alkaloid by percolating the leaves with water acidulated with sulphuric acid, and treating the percolate with ether and carbonate of soda in the usual way. The ethereal extract obtained by using this process also failed to crystallise spontaneously. In certain experiments I used acetic acid for acidifying the alcohol employed for percolating the leaves, but the ethereal extract also failed to crystallise. These experiments appeared to me to be sufficiently exhaustive to indicate that it was not the method of extraction employed which prevented the alkaloid from crystallising. I have already indicated that in curing the leaves heat was used, and it appeared to me that possibly the temperature employed might have been sufficiently high to cause decomposition of a portion of the alkaloid present in the leaves. In order to test the correctness of this supposition, I obtained from Mr. Blechynden a sample of fresh leaves grown in the Society's Gardens at Alipore. These leaves were plucked in the morning, and when received by me a few hours later were still perfectly green. I divided the sample into three portions—one portion, A, was reduced to pulp and extracted with alcohol, &c., in the usual way. The second portion, B, was first partially dried by being exposed to the air in the laboratory for four days, the temperature varying between 85° and 90° F. The leaves were then placed in a water-oven and heated to 100° C. for six hours. The remaining portion, C, was dried under a hot plate at a temperature of 77° C., with free exposure to air. The results obtained on analysis are shown in Table No. V.

TABLE NO. V.

Sample.	Moisture.	Ash.	Total alkaloid.	Total alkaloid calculated on anhydrous leaves.
A	66'09	3'09	0'330	0'973
B	1'27	—	1'004	1'01
C	3'14	—	1'035	1'06

In sample B the ethereal extract was of a much darker colour than that yielded by the other two samples; physiologically there was no difference as far as I could ascertain between the different extracts. The ethereal extract from the sample in which the undried leaf pulp had been used, had an odour not unlike that of Indian hemp extract, which was very marked, and which was to a considerable extent absent from the other extracts. These three extracts, however, all failed to afford any indication of crystallisation. I made several experiments, using alcohol, chloroform, &c., as solvents for the ethereal extract, in the hope of obtaining a crystalline alkaloid, but with negative results.

The ethereal extracts obtained in the course of my experiments were easily soluble in dilute hydrochloric acid, but the hydrochloric acid solution also failed to afford on spontaneous evaporation a crystalline salt. Certain samples of the hydrochlorate of cocaine solution I dried over concentrated sulphuric acid, a transparent faintly yellow varnish-like mass was the result, which was decidedly hygroscopic on exposure to air. Other samples I evaporated on a water-bath at a low temperature, also with negative results, as far as a crystalline product was concerned. I found, however, that by using the full heat of a water-bath and constantly stirring the solution, that a sticky mass was obtained which on cooling was brittle and could be rubbed to a powder; but this powder was hygroscopic, and a short exposure to air was sufficient to convert the powder into the original sticky varnish-like body.

In a paper by Dr. Howard in the *Pharmaceutical Journal*, to which I have already referred, a method is described for the separation of cocaine from the amorphous matter of an alkaloidal nature with which it is stated often to be associated by means of platinic chloride. According to Howard platinic chloride precipitates both cocaine and the amorphous alkaloid, but while the double chloride of cocaine and platinum forms a salt soluble in water at 80° C., the amorphous platinum compound is insoluble under similar treatment. On analysing these platinum compounds Howard obtained 19.16 per cent of platinum from the soluble salt, and 18.54 per cent of platinum from the insoluble compound. The percentage of platinum obtained from the soluble platinum salt corresponds fairly with that which should be yielded by a salt having the composition $(C_{17}H_{21}NO_4HCl)Pt_2Cl_4$, and Howard states that the base giving the soluble platinum salt is cocaine. The base, on the other hand, obtained from the insoluble platinum salt is described as being extremely bitter, gives no crystallisable hydrochlorate, and produces no anæsthetic effects. It is not the hygrine described by Lossen, because that base affords a hydrochlorate which crystallises freely, has no bitter taste, and gives a platinum salt which is decomposed by heating the liquid. Howard on these data concludes that the base giving the insoluble platinum salt probably contains three atoms more of carbon than cocaine; and that amorphous cocaine has no existence, but is a solution of cocaine in the base above described. In order to test the correctness of the views advanced by Howard, I made some experiments with the platinum salts of the alkaloids extracted from the coca leaves. And first as regards the solubility of the two platinum compounds: I found that even using water at 15° C. for washing the precipitate produced by platinum chloride in a hydrochloric acid solution of the bases, it was practically impossible to determine at what point to stop washing the precipitate, for on using a large volume of water, very little insoluble residue was left on the filter. I prepared a solution of the ethereal extract of the leaves in dilute hydrochloric, taking care to avoid an excess of acid being present in the liquid; this solution was precipitated with an excess of platinum chloride, and largely diluted with water. The solution was then filtered, and the residue on the filter well washed with water. The filter with its contents was dried over sulphuric acid in vacuo; the platinum salt yielded on analysis the following percentage of metallic platinum:—0.0992 grm. gave 0.0186 grm. platinum, equal to 18.75 of platinum calculated on the salt. A second lot of ethereal extract, treated in the same manner, gave a platinum salt which afforded the following percentage of platinum on ignition:—

- I. 0.1776 grm. gave 0.0336 grm. platinum.
II. 0.2420 " " 0.0460 " "

These results are equal to 18.91 and 19 per cent of platinum respectively calculated on the salt. The three analyses of the insoluble platinum salt agree fairly, and give a mean of 18.88 per cent of platinum in the compound.

In order to determine the composition of the soluble platinum salt I recovered the base from the filtrate and washings of the insoluble platinum salt, by adding ammonia and agitating with ether. The ethereal extract was neutralised with hydrochloric acid, and precipitated with platinum chloride, from a concentrated solution. The precipitate was washed with ice-cold water, and finally dried over sulphuric acid in vacuo. On igniting the platinum salt the following results were obtained:—

- I. 0.1776 grm. gave 0.0334 grm. platinum.
II. 0.0962 " " 0.0180 " "

equal to 18.80 and 18.71 per cent of platinum calculated on the salt, and a mean of 18.75 per cent for the two experiments. Howard found that the alkaloid present in the soluble platinum compound had the properties of cocaine, while that present in the insoluble platinum salt was another base which produced no numbing effect on the tongue. My experiments with coca leaves grown in India are not in accord with those of Howard: I found the base extracted both from the soluble and insoluble platinum compound produced a marked anæsthetic effect on the tongue. In one of my experiments the alkaloid obtained by decomposing the soluble platinum salt yielded on spontaneous evaporation of its ethereal solution a few star-shaped crystals, and this was the only instance in which I obtained a crystalline base on spontaneous evaporation. O. Hesse, in a paper on "The Alkaloids of Coca leaves,"* states that from the amorphous portion of the coca bases which can be easily separated from cocaine, he obtained a platinum salt that yielded, in two experiments, 18.26 and 18.44 per cent of platinum, the amount of water being respectively 5.0 and 5.5 per cent. Calculated on the anhydrous salt this would be equivalent to 19.22 and 19.51 per cent of platinum, and accordingly the amorphous base would appear to have the same composition as cocaine. Hesse also states that this amorphous material is not homogeneous, since he was able to separate from it by fractional precipitation a well-defined base, which he calls cocaine, but which he was only able to obtain from a small leaved variety of coca. This base has also the same empirical formula as cocaine. The hydrochlorate of this base is amorphous, but it yields a crystalline platinum salt containing four equivalents of water of crystallisation which is only lost at 120° C. Howard does not state the temperature at which his insoluble platinum salt was dried; if it was dried over sulphuric acid, in the same manner as the soluble platinum compound, it was probably not anhydrous, and hence yielded a lower platinum percentage than the soluble platinum salt. The mean platinum content of the three insoluble platinum compounds I examined is equal to 18.88 per cent compared with 18.75 of platinum in the soluble platinum salt. All my platinum salts were dried over sulphuric acid in vacuo, and were probably not anhydrous. Possibly my platinum salts were mixtures of the hydrochlorates of cocaine, with Hesse's base cocaine. And this assumption would also be borne out by the fact that I have obtained, by operating with a sample of alkaloid extracted from leaves grown in a different district to those employed for the isolation of cocaine used in the experiments I have already quoted, a soluble platinum salt which yielded, after drying in vacuo over sulphuric acid, 19.3 per cent of platinum on ignition. The amount of alkaloid at my disposal was very small, and I was unable to make duplicate analyses, or to estimate the amount of platinum in the so-called insoluble platinum compound. I would suggest as an explanation of the fact of my platinum percentages for the soluble platinum salts used in the first experiments being lower in platinum than the percentage which should theoretically be yielded by the hydrochlorate of cocaine and platinum being due to the varying amounts of Hesse's base cocaine contained in Indian grown coca leaves.

John Williams, in the *Pharmaceutical Journal*, September 24, 1887, describes a method of testing the hydrochlorate of cocaine for impurities. The method he recommends depends upon the almost absolute insolubility of the hydrochlorate of cocaine in ether, and the fact that most, if not all the ordinary salts or impurities appear to be soluble in ether when converted into hydrochlorate. In order to apply the test, the hydrochlorate is dissolved in the smallest quantity of absolute alcohol, and to this solution about six times the volume of pure anhydrous ether is added, and the mixture well shaken. Under these conditions the hydrochlorate of cocaine separates as a crystalline precipitate, while the impurities remain dissolved in the ether. Operating in the manner described by Williams, I found that the hydrochlorate of the crude alkaloids extracted by Squibb's method contained only 2.89 per cent of impurity. The action of ether, however, on the absolute alcohol solution of the hydrochlorate was different to that described by the author. On the addition of ether to the alcoholic solution no crystalline precipitate was produced, the base adhered to the sides of the flask at first in what had the appearance of minute crystals, and these crystals rapidly coalesced and formed minute globules, and this result also ensued when a larger volume of ether was used than that ordered by Williams. Under the circumstances it was impossible to collect the hydrochlorate of cocaine on a filter.

In estimating the alkaloids contained in coca leaves, and using relatively the same amount of solvent and leaves in all the experiments, I was struck with the variations in the amount of coca-tannic acid present in the various samples. On adding ether to the acidulated alcoholic extract to remove colouring matter, and in many instances on allowing the mixture to stand, the coca-tannic acid separated out as a sulphur-yellow deposit on the sides of the bottle. It was also of interest to note that the largest deposits of coca-tannin occurred in those samples which yielded the highest percentage of alkaloid. It appears to me, therefore, as not improbable that in the leaves the cocaine is in combination with the acid to which this term coca-tannic has been applied.

There is one last point to which I would refer in connection with the chemistry of the extraction of cocaine from the leaves. The volatile base hygrin has often been mentioned in this communication. I endeavoured to isolate it from the fresh and undried leaves by distillation with water. The distillate had the peculiar odour of the leaves, was distinctly acid in reaction, and failed with the usual alkaloid reagents to afford the slightest indication of the presence of a basic principle.

(In the "Report on the Progress and Condition of the Government Botanical Gardens and Parks, Nilgiris, for 1884-5," it is stated that two big bushes of *E. coca* exist at Barliyar, where they grow freely, but fruit sparingly. Mr. Hopper, the Government Quinologist, has analysed three samples of the leaves taken from these bushes. In his first attempt to isolate the alkaloid in a crystalline state he was unsuccessful; in his second attempt he succeeded in obtaining the alkaloid crystalline, but with an admixture of some acrid principle, which rendered it useless as an anæsthetic; his third attempt ended in complete success, and the alkaloid manufactured by him has been used, and approved of, by Dr. Brockman in his surgical ophthalmic operations. Mr. Hopper obtained 0.5 per cent of alkaloid from the leaves).

(To be continued).

Why Rails in Use Rust less quickly than Rails at Rest.—W. Spring.—The preservation of rails in use is not the result of vibratory motion, or of an electric action due to the passage of the trains, but to the formation of magnetic oxide produced by the compression of the rust on the metal. The rails are thus protected against the action of moist air in the same manner as is iron oxidised by fire.—*Bull. de la Soc. Chim. de Paris.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, November 15th, 1888.

Mr. WILLIAM CROOKES, F.R.S., President, in the Chair.

CERTIFICATES were read for the first time in favour of Messrs. Carl Duisberg, Ph.D., Farbenfabriken, vormals Bayer and Co., Elberfeld; Lionel Remond Lenox, Ph.D., Lehigh University, South Bethlehem, Pennsylvania; George Lloyd, 25, Kensington Gardens, Baysall Heath, Birmingham; James Muir, Staunton Harold, Branksome Park, Bournemouth; Robert Hodgson Parker, 26, Harford Street, Norwich; John Percival, B.A., 58, Harwood Road, Walham Green, S.W.; Percy Andrew Ellis Richards, 44, Sinclair Road, Kensington; Emanuel Roberts, Moratna, Ceylon.

The following were duly elected Fellows of the Society:—Messrs. Walter Bromley Cooley, John Burke Fairley, Walter M. Gardner, Archibald Carlyle Mounsey Ingram, Frank Pullinger, A. Alexander Ramsay, Clement J. Rhodes, C. Heinrich Trinks.

The following papers were read:—

79. "*The Principles of Thermochemistry.*" By S. U. PICKERING.

The author rejects the thermochemical principles enunciated by Thomsen, Naumann, and Berthelot, not only on special grounds, but on the more general ground that they depend on an impossible distinction between chemical and physical actions. A satisfactory explanation of all known thermochemical facts is derived from the recognition of the laws of dissociation and the hydrate theory of dissolution. Every act of combination must be accompanied by the evolution of heat, and in interactions where heat is absorbed this absorption must be due to the fact that one or more of the agents being partially dissociated at the temperature of the interaction, the removal of one of the products of the dissociation necessitates a further decomposition of the agent. The heat evolved must also be a direct measure of the affinities saturated, and, of two possible interactions, that which evolves more heat must occur to the exclusion of the other.

The cases of endothermic changes which present difficulties are those in which liquids and solids are concerned. The heat absorbed when many solids are dissolved in liquids cannot be explained by the fusion, but only by the volatilisation of the solid. A mass of water contains some fundamental molecules possessing an energy of 10,000 cal. greater than the average molecular aggregates constituting the mass. These can therefore combine with the salt, and effect its volatilisation with an evolution of heat, even if the heat of volatilisation be nearly 10,000 cal.; other water aggregates then dissociate to supply the place of the free molecules thus removed from the sphere of action.

From theoretical considerations the author arrives at the conclusion that Berthelot's theory as to the division of a base between two acids is correct—that two acids present in equivalent proportions should divide the base equally between them; that, since sulphuric acid acts as a monacid in this respect, H_2SO_4 should be compared with HCl and not with $2HCl$; and that if one of the two acids form a dissociable salt, it would take none or very nearly none of the base. The facts observed, the author argues, are in accordance with these conclusions, and are entirely opposed to the existence of the so-called "avidity" or "affinity" constants advocated by Ostwald and others.

The reason why sulphuric acid acts as a monacid in this respect, or in other words why H_2SO_4 and K_2SO_4 interact to form $2HKSO_4$ in spite of the absorption of heat accompanying the action, is that lower hydrates (especially

of the acid) are present, and that with these lower hydrates the interaction is exothermic, and therefore necessarily occurs, the absorption of heat noticed being due to the dissociation of the higher hydrates to supply the place of the lower ones thus removed from the sphere of action.

DISCUSSION.

Professor RAMSAY said that it was merely a matter of nomenclature to distinguish physical attraction, in which each molecule present attracted every other molecule according to some law comparable with the law of gravitation from chemical attraction, in which selective attraction is exercised; but that he preferred to draw the distinction, where possible, in order to save confusion, though it might be difficult in some cases to do so. He did not believe in the universal presence of complex molecules in liquids and solids; nor did he exclude the existence of such; the researches of Professor Young and himself, he thought, conclusively established the absence of a complex molecular structure in such liquids as ethyl alcohol and ether; while on the other hand Henry's arguments testified to the complexity of the molecules of certain oxides, such as silica. And with regard to water, which specially formed the subject of Mr. Pickering's remarks, while the vapour-density pointed to molecular simplicity, other arguments drawn from its behaviour when examined by Raoult's method were in favour of moderate complexity.

Dr. ARMSTRONG said that he agreed with Mr. Pickering, and thought that it would be necessary in the future to attach a far wider significance to the term chemical action, and to greatly restrict the use of the term physical action—that, in fact, very many so-called physical changes would be found to involve a change in molecular composition or configuration. It was conceivable that in certain cases such as Professor Ramsay had mentioned, molecule acted upon molecule chemically, but in such manner that the molecular aggregate was of the dimensions of the mass. By taking into account the action of water, Mr. Pickering had advanced what appeared to be a rational explanation of many facts which hitherto had appeared paradoxical.

Mr. PICKERING, in reply to Professor Ramsay, said that the fact that gaseous water was of normal density appeared to him compatible with the existence of complex water molecules: probably a sudden change attended liquefaction or gasification. This argument might be of general application.

80. "*Note on the Mixture of Propyl Alcohol and Water.*" By Professor RAMSAY, F.R.S., and Professor YOUNG.

Chancel has called attention to the fact that a mixture of propyl alcohol and water in the proportions $C_3H_7O : H_2O$ distils over to the last drop at 87.5° (press.=738 m.m.). Konowalow, however, determined the vapour-pressure of mixtures of the alcohol and water, and arrived at results adverse to the conclusion that a definite hydrate exists, and the authors are of similar opinion. They found that the vapour-pressures of the mixture determined by the static method were uniformly higher than those determined by the dynamical, but the difference is very small and far less than is observed with most dissociating substances, the behaviour being more nearly that of an imperfectly purified stable substance. The results of vapour-density determinations seemed to point to a rise of density with fall of temperature and increase of pressure, but it was afterwards found that the greater part of the rise was due to condensation, probably of water, on the side of the tube. A percentage contraction of 1.85 was observed on mixing the alcohol with water—71.46 per cent alcohol to 28.54 per cent water. The composition of the mixture of constant boiling-point was found to vary with the pressure under which it was distilled.

DISCUSSION.

Mr. HOWARD expressed the opinion that propyl alcohol and water formed a definite compound until vaporized;

the behaviour of the various lower alcohols with water, and the fact that the solubility of amyl alcohol in water diminished as the temperature rose, all tended to prove that the alcohols formed hydrates.

Professor YOUNG, in support of the opinion that the mixture was not a hydrate, recapitulated the arguments which he and Professor Ramsay had advanced in previous papers in discussing the properties of various liquids and liquid mixtures.

81. "*Note on the Action of Nitric Acid on Ammonium Chloride.*" By F. G. MATHEWS, Ph.D.

The principal gaseous product of the action of nitric acid on ammonium chloride in solution is nitrous oxide, and not nitrogen, as has been previously stated; the gas is mixed with small quantities of chlorine and oxychloride of nitrogen, from which it may be freed by washing with sodium hydroxide. The nitrogen of the nitric acid, as well as of the ammonium chloride, is concerned in the formation of the nitrous oxide. The interaction is of general application, and takes place in all cases in which a solution of an ammonium salt is heated in the presence of nitric acid and hydrogen chloride.

82. "*Ethylcinnamyl-diethacetate.*" By F. G. MATHEWS, Ph.D.

A simpler method of preparing ethylcinnamyl-diethacetate than has been previously known is to allow a mixture in molecular proportions of benzaldehyde and ethylcinnamyl-diethacetate saturated with hydrogen chloride to stand for about a month: the product separates slowly in crystals which are practically pure ethylcinnamyl-diethacetate. On hydrolysis with barium hydroxide, cinnamic and diethacetic acids are produced, small quantities of a ketone only being formed. An attempt to prepare the corresponding monethyl-derivative in a similar manner failed. On trying to prepare similar derivatives of ethylic, mono-, and di-methacetoacetate, no products could be isolated, the action appearing to be more complex than in the case of the corresponding ethyl compounds.

83. "*The Isomeric Sulphonic Acids of Betanaphthylamine.*" By ARTHUR G. GREEN.

It is known that on sulphonating betanaphthylamine by means of ordinary sulphuric acid, a mixture of α - and γ -acids is produced at low temperatures, and at higher temperatures (160 — 170°) a mixture of β and δ : according to the formulæ usually assumed for these acids, the first pair have their sulpho-groups in α -positions, the second pair in β -positions; and their formation is exactly analogous to that of the α - and β -sulphonic acids of naphthalene. According to Dahl, the product at 100° consists of α -, β -, and γ -acids, but the author finds that, as was to be expected, the δ -acid is also present. The four acids can be readily isolated by a slight modification of Dahl's process. The ammonium salts of the four acids were found to differ in a very characteristic manner: that of the β -acid is less soluble than the three isomeric salts, and by means of this salt the β -acid was obtained in a pure state, and was found to crystallise in prismatic needles, not in nacreous plates, the formation of which is shown to be dependent on the presence of δ -acid. Although betanaphthylamine gives four isomeric acids on sulphonation, only two sulpho-acids are supposed to be formed by sulphonating betanaphthol; but bearing in mind the analogous behaviour of hydroxy- and amido-compounds, it would appear much more probable that four acids are formed in the latter case also, and hence a search was made for the δ -sulphonic acid in the product of sulphonation of betanaphthol at 100° . As the separation of isomeric betanaphtholsulphonic acid presents great difficulties, the method adopted consisted in converting the sulphonation product into the corresponding betanaphthylaminesulphonic acids and separating these. By this means it was proved that the product formed at 100° is a mixture of the β - and δ -isomers. Hence at higher temperatures, at any rate, betanaphthol behaves on sulphonation like betanaphthylamine; whether

this is the case at low temperatures also remains to be seen.

DISCUSSION.

Mr. WYNNE asked whether Mr. Green had any evidence in favour of the formulæ he had adopted for the α (Badische) and γ (Dahl) betanaphthylaminesulphonic acids. The γ -acid was more usually represented by the formula $\text{NH}_2 : \text{SO}_3\text{H} = 2 : 1$. With regard to the α or Badische acid, it was to be noted that Cleve had assigned the constitution adopted by Mr. Green to the dichloronaphthalene melting at 34° ; that Forsling had assigned the constitution $1 : 3$ or $1 : 2$ to the dichloronaphthalene melting at 61.5° , obtainable from the Badische acids; and that Erdmann and Kirchhoff had obtained a dichloronaphthalene melting at 61.5° , which was unquestionably heteronuclear. At present, therefore, Mr. Green's formula for the betanaphthylamine- α -sulphonic acid could not be accepted.

Looking at the variation in the proportions of the four betanaphthylaminesulphonic acids formed on sulphonating at different temperatures, Mr. WYNNE suggested that the conversion of the α - and γ -acids into the β - and δ -acids at 160° might be explained by supposing that in the presence of the sulphuric acid the α -acid was converted exclusively into the β -acid, and that the γ -acid underwent a similar change into the δ -acid, which itself at higher temperatures (or by a prolonged action of the sulphuric acid at 160°) would undergo conversion into the β -acid. Such a change, though perhaps different in its course, would be analogous in result to that described by Professor Armstrong and himself in the case of the monosulphonic acids of the β -halogen-derivatives of naphthalene, having a constitution similar to that of the Badische acid.

Dr. ARMSTRONG referred to Emmert's observation that the betanaphthol α -sulphonic acid corresponding to betanaphthylamine- α -sulphonic acid is convertible into a dihydroxynaphthalene different from hydrobetanaphthoquinone, as incompatible with the conclusion that the α -acid was the $1 : 2$ compound; moreover, an acid in which the SO_3H and OH groups were in the relative positions $1 : 2$ would not, he thought, be capable of forming azo-colours. He then pointed out that the conclusions at which Mr. Wynne and he had arrived concerning the constitution of the dichloronaphthalene obtainable from the Badische acid, were irreconcilable with Mr. Green's formula (cf. the following Abstract).

Mr. GREEN, in reply, defended the view that the α -acid was the ortho-compound mainly on the ground that it and the corresponding hydroxy-acid differed so greatly in properties from their isomers.

84. "The Constitution of the Dichloronaphthalenes, especially the $\alpha\beta$ -Compounds." By HENRY E. ARMSTRONG and W. P. WYNNE.

The three possible $\alpha\alpha$ - and the two possible heteronuclear $\beta\beta$ -dichloronaphthalenes are all known, and not only are they known, but there can be little doubt that the formulæ now ascribed to the several modifications (comp. *Abstracts of Proceedings*, 1888, p. 95) are correct expressions of their constitution.

The object of the present note is to point out that the four possible $\alpha\beta$ dichloronaphthalenes are also known, and to draw attention to the explanation of the somewhat discrepant statements on record relating to the so-called θ -modification, melting at about 61° . This was first prepared by Cleve, who obtained it from one of the three α -nitro-acids formed on nitrating naphthalene- β -sulphonic acid; he subsequently obtained a dichloronaphthalene having the same melting-point from a second of these three acids, but left it an open question whether two isomers of the same melting-point existed, or whether an isomeric change took place on treating the nitrosulphochloride with phosphorus pentachloride. Dichloronaphthalene melting at about 61° has since been prepared (1) by Arnell from β -chloronaphthalenesulphonic acid; (2) by Cleve from dichloralphanaphthylamine; (3) by Claus from betanaphthol- α -sulphonic acid (Bayer's

modification); (4) by Forsling from betanaphthylamine- α -sulphonic acid (the Badische acid); (5) by Erdmann and Kirchhoff from parachlorophenylparaconic acid. Forsling has quite recently stated (*Berichte*, 1888, 2802) that the modification melting at about 61° is either $1 : 2$ or $1 : 3$ dichloronaphthalene, his conclusion being doubtless based on Cleve's statement that dichloralphanaphthylamine yields phthalic acid on oxidation, and is therefore to be regarded as homonuclear. Now the authors have found (*British Association Report*, 1887, p. 231) that two distinct dichloronaphthalenes have been regarded as one, and that while that from dichloralphanaphthylamine melts at 61.5° , that from Arnell's β -chloronaphthylenesulphonic acid and from the Badische or betanaphthylamine- α -sulphonic acid melts at about 64° ; the chloride of the acid obtained on sulphonating the former melts at about 148° , the isomeric sulphochloride obtained from the latter melting at 119° . In support of Cleve's statement that dichloralphanaphthylamine is a homonuclear compound, they are able to state that it yields the same trichloronaphthalene (m. p. 92°) as dichloralphanaphthol, an undoubted homonuclear derivative. The dichloronaphthalene melting at 61.5° is, therefore, either the $1 : 2$ or the $1 : 3$ homonuclear modification. That melting at 64° must be regarded as the $1 : 2'$ or $1 : 3'$ heteronuclear modification, inasmuch as the dichloronaphthalene melting at 34° , discovered by Cleve in 1887, is also a homonuclear compound.

The dichloronaphthalene melting at 34° was obtained by Cleve from chlorobetanaphthylamine and from chlorobetanaphthol; it may also be prepared from the chloralphanaphthylamine which Cleve obtained by reducing dichloralphanaphthylamine. Cleve's statement that chlorobetanaphthylamine is a homonuclear compound, since it yields phthalic acid on oxidation, is confirmed by the observation that a sulphonic acid may be prepared from chlorobetanaphthol, which is converted on treatment with bromine into a bromhydroxyquinonesulphonate, identical with that which may be obtained from Schæfer's betanaphtholsulphonic acid, in which the bromine is undoubtedly present in the quinone nucleus.

The fourth $\alpha\beta$ and the second heteronuclear dichloronaphthalene is the η -modification, melting at 48° . This was originally obtained by Cleve from one of the three α -nitro-derivatives of naphthalene- β -sulphonic acid; it has since been prepared by Forsling from betanaphthylamine- γ -sulphonic acid (Dahl's modification), and synthetically by Erdmann and Kirchhoff. The authors have recently obtained it by distilling their β -naphthalenedisulphonic acid (*Abstracts of Proceedings*, 1886, p. 231) with phosphorus pentachloride; attention is to be called to the fact that this had previously been stated to be a method of preparing the θ -modification, melting at 61.5° (*Brit. Assoc. Report*, 1887, p. 232); how the mistake arose they are unable to explain, but a mistake was undoubtedly made, as a portion of the original specimen of the sulphochloride, melting at 150° , referred to in the British Association Report, gave on hydrolysis η - and not θ -dichloronaphthalene. The sulphochlorides prepared from the two dichloronaphthalenes melting at about 48° and 61° respectively have the same melting-point, and hence the mistake was overlooked until recently, when a large quantity of disulphonic acid was prepared and converted into dichloronaphthalene.

It being determined that the two modifications melting at 34° and 61.5° are the two possible homonuclear $\alpha\beta$ -dichloronaphthalenes, it remains only to ascertain which is the $1 : 2$ and which is the $1 : 3$ compound; the authors have succeeded in solving this problem somewhat unexpectedly by studying so-called α -dichloronaphthalene, m. p. 38° , which is obtained on heating naphthalene tetrachloride with alcoholic potash. On sulphonating this compound, two isomeric sulphonic acids are formed, the chlorides of which melt at 133° and 148° , but as these are the melting-points of the chlorides formed from the acids which result on sulphonating β -dichloronaphthalene

(m. p. 68°) and θ -dichloronaphthalene (m. p. 61.5°) respectively, the two sulphochlorides from α -dichloronaphthalene were hydrolysed; that melting at 148° gave θ -, and that melting at 133° β -dichloronaphthalene, proving the supposed uniform α -dichloronaphthalene to be a to be a mixture of θ and β . From this it follows, as only a single $\alpha\beta$ homonuclear dichloronaphthalene can be obtained from naphthalene tetrachloride, viz., the 1:3 modification, that θ -dichloronaphthalene melting at 61.5° is the 1:3 derivative, and that melting at 34° must be regarded as the 1:2 derivative. This conclusion is supported by Widman's observation (*Bull. Soc. Chim.*, xxviii., 506; *Ber.*, 1882, 2160) that α -dichloronaphthalene yields two tetrachlorides—one an oil yielding γ -tetrachloronaphthalene, the second a crystalline solid melting at 172° , indistinguishable from that obtainable from β -dichloronaphthalene. It is also confirmed by the observation that on hydrolysing the dichloronaphthalenesulphonic acids prepared, in accordance with Widman's directions, from naphthalene- α - and β -sulphonic chlorides, θ -dichloronaphthalene, melting at 61.5° , is obtained from the α -acid, and β -dichloronaphthalene from the β -acid.

At present the data are not sufficient to determine whether the heteronuclear modification, melting at 48° , is the 1:3, and that melting at 64° the 1:2 derivative, or *vice versa*. Erdmann and Kirchhoff have indeed put forward the view that η -dichloronaphthalene is the 1:3 modification, but their method cannot be regarded as trustworthy, as the origin of the hydroxyl in their naphthol derivatives cannot be determined. The authors anticipate that the study of the sulphonic acids of the dichloronaphthalenes, in which they have long been engaged, will lead to results which will permit of the constitution of isomerides such as the η and the isomeric heteronuclear $\alpha\beta$ -dichloronaphthalenes being determined beyond question.

85. "Piazine-derivatives." By Dr. ARTHUR T. MASON. In this paper, which is an account of a continuation of work described in the *Berichte*, xx., 267, the author adopts Widman's nomenclature (*J. Pr. Chem.*, xxxviii., 135): the "Ketines" (V. Meyer), "Pyrazines" (Wolff, Mason), "Aldines" (V. Meyer), and all compounds containing a ring of four carbon-atoms and two nitrogen-atoms in para-position are now termed *Paradiazines* or *Piazines*.

The author finds that the condensation product obtained from phenanthraquinone and ethylenediamine is not a dihydride, as formerly stated, but the base *phenanthra-piazine*.

Diphenylpiazinedihydride, prepared from benzil and ethylenediamine, which is very unstable towards acids, gives on distillation a very stable base (2, 3) *diphenylpiazine*; this crystallises from 50 per cent alcohol in large colourless plates, melting at $118-119^{\circ}$; it is only a weak base. The chloroplatinate, $C_{16}H_{12}N_2 \cdot PtCl_6$, forms long yellow prismatic needles.

By the action of sodium on a solution of 2, 3 diphenylpiazine in amyl alcohol, two hydrides were obtained of the formula $C_{16}H_{18}N_2$. α (2, 3) *Diphenylpiazinehexahydride* crystallises from light petroleum in long slender white needles, melting at $122-123^{\circ}$, and possesses strong basic properties. The hydrochloride, $C_{16}H_{18}N_2 \cdot 2HCl$, forms long glistening white needles, melting at 310° . The chloroplatinate, $C_{16}H_{18}N_2 \cdot H_2PtCl_6 + \frac{1}{2}H_2O$, forms golden-yellow prismatic needles. The nitroso-derivative, $C_{16}H_{16}N_2O_4$, crystallises in white prismatic needles melting at $142-143^{\circ}$. Methyl iodide gives with the α -hydride the hydriodide of (1, 4) dimethyl (2, 3) diphenylpiazine tetrahydride, $C_{18}H_{22}N_2HI$, which forms long colourless needles; the base of this salt crystallises from hot water in long colourless needles melting at $263-264^{\circ}$; the chloroplatinate, $(C_{18}H_{22}N_2)_2 \cdot 3HCl(PtCl_4)_2 + 8H_2O$, forms yellow prismatic needles. β (2, 3) *Diphenylpiazinehexahydride*, which is found in the mother-liquors from which the α -compound has separated, together with a third basic hydride, crystallises from 50 per cent alcohol in long silky white needles, which on drying become dull

white. It melts at $108-109^{\circ}$, and has strong basic properties. The hydrochloride, $C_{16}H_{18}N_2 \cdot 2HCl$, forms colourless prismatic needles, melting at 295° . The chloroplatinate, $C_{16}H_{18}N_2 \cdot 2HClPtCl_4 + 2H_2O$, forms long light yellow needles. On oxidation (2, 3) diphenylpiazine yields a *phenylpiazinecarboxylic acid*, melting at about 202° , which yields well-characterised salts.

The author, in conjunction with Mr. L. A. Dryfoos, is extending the research to the α -diketones of the fatty series.

At the next meeting, on December 6th, there will be a ballot for the election of Fellows, and the following papers will be read:—

"A Method of determining Vapour-densities applicable at all Temperatures and Pressures." By Dr. W. Bott.

"Derivatives and Some New Colouring-matters obtained from α -Pyrocresol." By Dr. W. Bott and J. Bruce Miller.

"The Action of Ammonia on Tungsten Oxychlorides." By Dr. S. Rideal.

PHYSICAL SOCIETY.

November 24, 1888.

Prof. REINOLD, President, in the chair.

THE REV. T. PELHAM DALE and Dr. R. M. Walmsley were elected members of the Society.

Capt. ABNEY read a paper "On the Measurement of the Luminosity of Coloured Surfaces," which was illustrated by experiments.

In a communication to the Royal Society General Festing and the author have described a method of comparing the intensity of the light of different parts of the spectrum reflected by various pigments with that reflected from white; and luminosity curves have been constructed, the areas of which give comparative measures of the total luminosities. This method of comparison is accurate, but requires considerable time, and the author has devised a more rapid process. The coloured surface, whose luminosity is to be compared with white, is placed beside a white patch within a dark box. A direct beam of light passes through an aperture in the box, and a black rod casts a shadow on the coloured patch; another beam from the same source is reflected at an angle, and forms a shadow of the same rod on the white patch, the junction of the two shadows coinciding with that of the two surfaces to be compared. In the path of the direct beam is placed a rotating disc with angular openings, adjustable whilst rotating by a simple lever, and by this means the white patch can be made to appear too light and too dark in rapid succession. By gradually diminishing the range of oscillation of the lever, a position of equal luminosities can be found. The coloured surface is now replaced by a white one, and the adjustment again made, and from the angular apertures required in the two cases the relative luminosities are determined.

Comparisons made in this way (the numbers relating to which are given in the paper) with emerald green, vermilion, French ultramarine, &c., gave results in close agreement with those deduced from the luminosity curves obtained by the spectrum method.

In reply to questions, Capt. ABNEY said the spectrum method was the more accurate, and could be relied on to one per cent. The new method gave results within two per cent, showing that the eye is very sensitive to small changes of luminosity when such changes take place in rapid succession.

Prof. RÜCKER made a communication "On the Suppressed Dimensions of Physical Quantities."

In arranging a system of dimensional equations for thermal quantities, the question arises as to what are the

dimensions of temperature. A degree of temperature as measured by the ordinary arbitrary method of the mercurial thermometer, is not affected by changes in the units of length, mass, and time, but the numerical values of thermal quantities (J for instance) depends on the scale of temperature adopted, say Centigrade or Fahrenheit. Two courses seem open, either of which renders a complete system of thermal dimensional equations possible. 1st, Temperature may be considered as a measure of energy, as in the kinetic theory of gases, and may be expressed as the energy of translation of a standard number of molecules, say that number contained in 1 c.c. of air at standard pressure and temperature; or 2nd, Temperature may be considered as a secondary fundamental unit. If the first be adopted, the dimensions of specific heat become M^{-1} , and the temperature of 0°C. is expressed by 1.5207×10^8 ergs. If a practical unit corresponding to $\frac{10^4}{18}$ ergs be adopted, this new unit of temperature will coincide with the Centigrade degree to about 1 part in 3000. The chief objection to such a definition of temperature is that the above relation between temperature and energy is not yet proved to hold for liquids and solids. If the second course be adopted the dimensions of all thermal quantities may be expressed in terms of M, L, T , and θ , where θ is the unit of temperature.

Attention was directed to the difficulties students generally experience on finding the dimensions of the same electrical quantities to be different, according as they are expressed in electro-static or electro-magnetic measure, and that different quantities may have the same dimensions. The anomalies are shown to be due to the suppression of the dimensions of specific inductive capacity and permeability, each being called unity in air. By retaining K and μ in the dimensional equations the author thinks that many difficulties will be avoided, the methods of transformation of units will be generalised, and the limits of our knowledge kept more clearly in view. Though the dimensions of K and μ cannot be determined, it is easily shown that those of the product $K\mu$ are $L^{-1} T$.

Mr. BLAKESLEY, in commenting on thermal units, strongly protested against the use of the word "*Therm*" as a name for the unit of heat. If used at all, it should be reserved for the unit of temperature. Referring to the choice of fundamental units, he reminded the Society that the dimensions of quantities expressed in the electrostatic or electro-magnetic systems become identical if the unit velocity be the velocity of light, and by choosing the unit of time as a suitable decimal part of a day, the relations between electrical and practical mechanical units could be simplified.

Prof. CAREY FOSTER, after discussing the effects of defining specific heat as a ratio, or as a quantity of heat on the dimensions of temperature, pointed out that as Quantity of heat = Temperature $\times$ Entropy, the dimensions of temperature would be determinate if those of entropy were found.

Prof. S. P. THOMPSON considered part of the difficulties of dimensional equations arose from the fact that no distinction was made between *scalar* and *vector* quantities. Thus the dimensions of work and moment of a force are given as $M L^2 T^{-2}$, whereas the true representation for the latter would be $M L^2 T^{-2} \sqrt{-1}$, because the line by which the force is multiplied is at right angles to the force. By similar considerations, Ampère's rule for the force between two current elements, can be derived from

the magnetic equation $\frac{m.m'}{r^2} = f$. For replacing m and m' by equivalent current elements, $i.ds$ and $i.ds'$, the equation becomes—

$$\int \frac{\sqrt{-1} i.ds \cdot \sqrt{-1} i.ds'}{r^2} \\ = \frac{-i^2 ds.ds'}{r^2}$$

Referring to the use of *Therm*, Dr. THOMPSON concurred with the remarks of Mr. Blakesley, and thought the word "*calorie*" answered all requirements. He also considered that thermal equations were greatly simplified by always expressing specific heat in ergs.

Prof. AYRTON was of opinion that students experienced much greater difficulty in dealing with electrical units than with thermal ones, and thought part of this was due to the vague way in which some of the standard text-books treated the subject. With reference to the force exerted by quantities of electricity, Prof. Perry and himself had pointed out that specific inductive capacity must be taken into account, for, contrary to Faraday, they had found it to be different in different gases.

In reply, Prof. RÜCKER said he often explained the identity of the dimensions of work and moment of a force, by considering moment as measured by the work done in rotating through unit angle, the dimensions of angle being zero as regards L, M , and T . He also pointed out that in Bayne's Thermodynamics specific heats are always expressed in ergs.

In thanking Prof. Rücker for his interesting paper, the President expressed his conviction that by paying attention to the points considered, the difficulties arising from the two systems of units would be considerably diminished.

OBITUARY.

DR. WALLACE.

THE death of Dr. Wallace, of Glasgow, which took place on the 5th inst., removes one of our most eminent and successful technical chemists. The deceased *savant* was generally recognised as an authority on sanitary questions, such as water supply, the air of towns, the disposal of sewage, the preservation of food, the hygienic construction of houses, and the germ-theory of putrefaction. But it is, perhaps, less widely known that he was an eminent expert in all questions connected with the manufacture, the analysis, and the utilisation of coal-gas. In the years 1868 to 1877 he was engaged in analysing gas-coal and in testing its practical value. His researches extended to upwards of 200 samples of Scottish coals, cannel, splints, and shales, as well as to similar minerals from Australia and from the United States and other foreign countries. He also studied very carefully the heating power of gas, gas-meters and governors, gas-burners, and lamps. Among other points, he established the fact that gas of low illuminating power is the most economical as a source of heat. Prior to the year 1876, Dr. Wallace was also busy with investigations bearing on the Scottish iron manufacture, and he made upwards of 2000 analyses of the raw materials, iron-stones, lime-stones, fire-clays, and furnace coal, as well as of the pig-iron and slags produced.

For many years he was also engaged in a study of the principles of sugar-refining, in which he was accepted as a leading authority.

The deceased chemist was a Fellow of the Royal Society of Edinburgh, of the Chemical Society, and of the Institute of Chemistry. He was for many years connected with the Glasgow Philosophical Society, the Presidency of which he held for three years. He was also an active member of the Society of Chemical Industry.

We must add that Dr. Wallace was no less esteemed in his private life than in his scientific and technical capacity.

JOHN COLLINS.

WE regret to announce the death, on the 28th of August last, of one of the most prominent chemists in Lancashire, Mr. John Collins, B.A., F.C.S., F.I.C., F.G.S., of Messrs.

Collins, Analytical Chemists and Consulting Chemical Engineers, Bolton, near Manchester. Mr. Collins was born in 1832 at Darton, in Yorkshire. He was educated at Chester College; and to the late Rev. Arthur Rigg, M.A., Mr. William Crookes, F.R.S., and South Kensington, he was indebted for his early scientific training. He was at one time Borough Analyst and Gas Examiner, and also Chemist to the Bolton Iron and Steel Co.; and while holding the latter position he worked out to a successful issue the Siemens-Martin and Bessemer processes. In the earlier years of his professional life he devoted much time to metallurgical matters; and he carried out a series of experiments on a most elaborate scale on the corrosion of steel and iron plates. He gave up his post as manager of the extensive steel work of the Bowling Iron Co. to continue his practice in Bolton. His profound knowledge of chemical and metallurgical work, together with his practical intimacy with engineering, metallurgical, and trade processes, generally secured him an extensive practice, and his opinion on patents, new processes, and so forth, was largely sought after.

Some twenty years ago he devoted special attention to water supply and pollution and sanitary matters, and in this branch of work he made a reputation. He patented a process for treating towns sewage called the "M and C Process"; this has been used for many years at Bolton and elsewhere with satisfactory results. His experience in litigation as an expert witness was very extensive, and he was a familiar figure in the committee rooms at Westminster and also the New Law Courts. He was an excellent lecturer, and had taken out, in association with his son, Dr. Walter H. Collins, many patents for improvements in trade operations.

Those who were intimate with him will find it difficult to name a man more equally or usefully accomplished. He had read deeply, and had observed men and manners in many countries.

NOTICES OF BOOKS.

An Essay on Cramming. By R. W. DAVEY and R. H. THOMPSON. London: John Walker and Co.

THE authors of this essay, like ourselves, regard the modern English system of competitive examination with dislike and suspicion. But, concerning the process commonly known as "cramming," and without which they rightly pronounce success almost impossible, they take a view, novel indeed, but which merits a fair scrutiny. It is commonly supposed that this cramming process is a great evil, and that crammers are an institution the country could very well do without. The authors, on the contrary, argue that the competitive examinations are the evil created by pedantic legislators, and that cramming is the remedy supplied by the common sense of the public. In this view there is, at least, a very considerable element of truth. They remind us that:—"The Civil Service Examiners, if left to themselves, would fill the Indian Service with decrepit students, unable to endure for a year the strain of real work in a trying climate; the crammer baffles them by his skill, enabling at least some men, of more vigorous nature, to obtain entrance. The examiners would crush out all originality and force beneath a solid weight of useless and musty learning; the crammer substitutes a structure so like the reality that it deceives the common enemy, but built of such light and airy materials that the moment the ordeal is passed it begins to dissolve into thin air, and the candidate is gradually able to recover his suspended animation and release his trammelled faculties. The examiner would reduce us in one generation to the condition from which China is only just beginning to awake; the crammer preserves for us some, at least, of the powers to which we

owe our existence as a nation, and our position as rulers of an empire."

We must remember that intellectual work, even of the most intense character, is not injurious, save when it is performed under the pressure of anxiety. But the unfortunate candidate who is preparing for an examination must be anxious, since a failure may ruin his prospects for life. Hence the effect upon the health of the student, successful or not, is ruinous.

Another point quite overlooked by the dominant pedantocracy is that examination may test a man's attainments, but not his powers; it may show us what he knows, but not what he can do. Now, save for the merest routine work—for which competent men might be obtained by lot—the great question is what a man can do. What are his resources, his power of origination? This is what we want in the civil administrator, in the military or naval officer, in the physician, the explorer, and the industrialist. But what reason have we to expect that the man who "passes" best—or passes at all—in a number of subjects, many of them quite irrelevant to his future life duties, will excel in suggestiveness? We fear that originality will be inversely as the power of "getting up" a given subject.

One remark of the author's deserves approving notice:—"Hitherto no editor has conceived it his duty to review the Examination Papers issued periodically by the Civil Service Commissioners, and to point out how a public interest so vital as the selection of our future officers is frequently left to the mercy of men whose chief object seems to be the display of their own erudition and the gratification of their own crotchets."

Of the remedial measures proposed by the authors, the following are important:—Direct responsibility of examiners and public criticism of their work, as also an imperative demand on part of the nation that absurd subjects, such as Latin and Greek verse, should be at once struck out. Poetry is an affair for one man in a million, and should not be required of others. But verse which is not poetry is beneath all contempt. Many other subjects demanded at examinations are little less absurd for the particular class of candidates in question.

Two further reforms Messrs. Davy and Thompson have overlooked, viz., the abrogation of "payment by results" in all grades of education, and the admission of original work as overriding all other considerations.

A New Course of Experimental Chemistry, including the Principles of Qualitative and Quantitative Analysis: Being a Systematic Series of Experiments and Problems for the Laboratory and Class-Room. By JOHN CASTELL-EVANS, F.I.C. London: Thomas Murby.

IN this book, which is one of Murby's "Science and Art Department Series" of text-books, the author makes some "introductory remarks" of considerable value. He tells us that "if he had simply added another to the so-called Text-Books in Chemistry, he would require considerably more ingenuity than he possesses in order to be able to make a suitable apology for such a very unnecessary proceeding." He goes on to say that "something was wanting which could not be supplied by any text-book or any practicable combination of existing books." Now this is what all the authors of text-books tell us explicitly or implicitly. They admit the multiplicity of existing elementary treatises, but they believe that something is wanting which they see the way to supply.

We certainly recognise that Mr. Castell-Evans proposes a course of instruction very different from those commonly adopted. He shows a full and clear acquaintance with the processes of experimental enquiry, and he seeks to train the student "to perform a quantitative experiment with a definite purpose in view." He tells us, most truly, that the best trained student is not he who has hoarded up the largest number of truths, but rather that one who

has become most expert in the use of the methods and means by which truths are found out." And in these few words he does in effect pronounce judgment on the system of "payment by results" (so-called), and on examinationism altogether. For no examiner can gauge the power of a pupil to find out truths; all he can do is to measure what quantity of knowledge he has accumulated. Our author refers to the Committee appointed by the British Association to inquire into the methods adopted for teaching chemistry. If this Committee will only say "drop payment by (pseudo-) results and let teachers no longer be hampered with the haunting nightmare "will such a method of instruction pay?" we shall soon see spring up, in place of our present examinees, a rich crop of discoverers, inventors, and appliers.

The instructions given in this book show a laudable attention to accuracy in every point.

CORRESPONDENCE.

ALKARSIN.

To the Editor of the Chemical News.

SIR,—I find that alkarsin (the mixture of the oxide with free kakodyle) is much more quickly prepared, and more easily, by distilling a mixture of white arsenic and carbonate of potash with glacial acetic acid than by the old slow method of distilling the white arsenic with acetate of potassium, which necessitates carefully heating the retort (otherwise it will break, the contents being dry) to redness.

The white arsenic will not decompose the acetic acid by itself; it must be in the presence of the carbonates, so that the moment the acetic acid and the carbonate decompose each other the arsenic may enter and combine with the methyl, partly in the form of kakodyle, and partly in the form of its oxide, the mixture of the two, as is well known, forming alkarsin.

Is cyanide of kakodyle formed by distilling a mixture of white arsenic and sodium cyanide with glacial acetic acid?

I have since found that arsenious cyanide, $\text{As}(\text{CN})_3$, is not formed by distilling one part metallic arsenic with six of mercuric cyanide, but only by the reaction of arsenious chloride on some cyanide; the cyanogen does not seem to combine directly with arsenic any more than it does with hydrogen, and perhaps that is the reason that cyanide of arsenic has not been previously discovered.—I am, &c.,

G. W. BLYTHE.

near Southport, Nov. 25, 1888.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 20, November 20, 1888.

The Nature of Milk. Reply to the Question:—"Does Milk Contain the Anatomical Elements of the Organisation, and do the Globules of Milk Rank among these Elements?"—A. Béchamp.—The author concludes that milk is not an emulsion. The milky globules are not bare globules of fat, but true free adipose vesicles. The milk of the cow contains, in addition to casein, other albumenoid matters not free, but dissolved

in combination with alkalies. Milk curdles spontaneously without the intervention of vibrios.

The Siliceous Compounds of Glucina.—P. Haute-feuille and A. Perrey.—In its combinations with silicon and potassium, glucina is replaced in all proportions by the alumina and ferric oxide, playing thus the part of a sesquioxide. In other compounds glucina acts as a protoxide.

Presence of Glycolic and Normal Propylene Dicarboxylic Acid in Suint.—A. and F. Buisine.—Not adapted for useful abstraction.

Bulletin de la Société Chimique de Paris.
Vol. 1, Nos. 4 and 5.

Action of Copper Acetylacetonate upon Carbon Oxychloride.—MM. Thomas and Lefèvre.—The authors have not yet decided whether the result of the reaction is tetracetylacetone or dimethyldiacetyl pyrone.

On Allotropic Arsenic. A Reply to Prof. Geuther.—M. Engel.—The molecular constitution of ordinary arsenic and that of the allotropic state appear to be respectively the same as those of red and white phosphorus. The specific gravity, 3.7, given by Prof. Geuther for allotropic arsenic is incorrect, and consequently the conclusions which he draws from this datum have no foundation.

The Volumetric Determination of Acids.—M. Engel.—In this note the author brings a claim to priority as regards the method proposed by M. Lenossier for the separation and volumetric determination of acids.

The Part played by Soda-lime in the Determination of Nitrogen.—M. Quantin.—The soda-lime process can yield good results provided we ignite rapidly and gently, and that only half the acid is saturated by the ammonia evolved.

Researches on the Sulphines.—G. Patein.—Not adapted for useful abstraction.

Acid Sulphates of Dimethylaniline and Diphenylamine. A General Reaction of the Acid Sulphates of Certain Aromatic Bases.—Leo Vignon.—The author describes dimethylaniline acid sulphate, dimethylaniline monosulphonic acid, diphenylamine acid sulphate, diphenylamine-monosulphonic acid, and discusses the formation of the acid sulphates of aniline, dimethylaniline, and diphenylamine. The formation of the mono-sulpho-conjugated acids of dimethylaniline and diphenylamine, obtained by heating the acid sulphates of these bases to 180° to 190° for two hours, seems to constitute a general reaction. Acid aniline sulphate, under the same conditions, is transformed almost quantitatively into sulph-anilic acid or aniline monosulphonic acid. This reaction is applied industrially for the preparation of sulphanilic acid. It seems therefore that the acid sulphates of aniline, and of the substituted amines derived from it, lose water at 180° to 190°, forming sulphonc derivatives.

The Production of Propylene Iodide in the Treatment of Glycerin with Iodine and Phosphorus.—H. Malbot.—The author, using red phosphorus, obtained a product which, when washed directly with soda without cohobation, had a volume of 135 c.c., and the density of 1.725. The proportions used were iodine, 300 grms., glycerin (sp. gr. 1.25), mixed with an equal volume of water, 200 grms., and phosphorus, 55 grms. The product was rich in isopropyl iodide. On adding only 10 per cent of water to the dry glycerin, the product obtained had the volume of 127 c.c. and the sp. gr. 1.99. It turned black very rapidly, even in the dark, and was very rich in propylene iodide.

Preparation of Epichlorhydrine.—Ad. Fauconnier.—Not suitable for abstraction.

Preparation of Ethylene Cyanide.—Ad. Fauconnier.—Three hundred parts of ethylene bromide are dissolved in 500 parts of alcohol, and the solution is boiled in a

reflux-apparatus. When it is a full boil, 200 parts of potassium cyanide in a saturated watery solution are let fall into it drop by drop. Each drop causes a precipitate of potassium bromide, and the reaction is completed in less than two hours. It is then let cool, the liquid poured off, and evaporated to dryness in vacuo on the water-bath. The residue is taken up in absolute alcohol and this alcoholic solution is distilled at first on the water-bath, then in the open fire, and in vacuo.

On Metallic Lustre.—W. Spring.—A metallic lustre is produced whenever a smooth surface is formed on a body sufficiently opaque. The more complete the opacity and the more perfect the smoothness of the surface, the more decided is the metallic lustre. But as there is probably no body absolutely transparent, so there is no body absolutely opaque. All depends on the degree of thickness in which we examine the substance. Between the vitreous lustre and the perfect metallic lustre there are all the gradations between transparency and opacity. Hence the metallic lustre does not in any way depend on the specific chemical nature of the substance, but on its physical condition.

Researches on the Glazes of Porcelain.—Ch. Lauth and G. Dutailly.—This valuable memoir does not admit of abstraction.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. Series 5, Vol. iii., No. 28.

This number contains no chemical matter.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Potassium Permanganate.—Can anyone inform me where to find the decision arrived at with regard to the molecular formula for potassium permanganate (i.e., whether KMnO_4 or $\text{K}_2\text{Mn}_2\text{O}_8$) by Raoult's cryoscopic method?—F. W. S.

Estimation of Oxygen in Metallic Copper.—Is this method known? I believe it is only a modification of Abel's. A weighed portion of the copper is immersed in a solution containing 30 grms. of nitrate of silver for four hours; at the end of this time the Cu is washed and withdrawn, the precipitate separated by filtration, and the amount of silver remaining in the filtrate determined gravimetrically.—CHEMICUS.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1515.

ON THE SPECIFIC HEATS OF GASES AT CONSTANT VOLUME.*

(PRELIMINARY NOTE).

By J. JOLY, M.A., B.E.

I HAVE found it possible to obtain the specific heat of a gas at constant volume by means of the steam calorimeter,† the values obtained being, I believe, reliable as close approximations to the true values.

The first method of procedure adopted was to compress by means of a pump a certain quantity of dry air into a thin copper sphere, the sphere being then closed by a screw valve. The quantity of gas in the sphere is ascertained by weighing.

The sphere is now hung in the calorimeter, suspended from a delicate balance, reading to one-tenth of a m.grm., and its thermal capacity determined in a certain number of experiments. The gas is then released, and the sphere further exhausted by means of an air-pump, sealed, and its thermal capacity again determined in a number of experiments. This allows of a computation of the thermal capacity of the contained gas.

This method I at first used, but, as in dealing with the effect on the weighings, due to the transference of so bulky a body from air to steam, much troublesome calculation and risk of error was involved, I modified it in the following manner:—

Two spheres are prepared, alike with respect to external volume, and approximately of the same weight. The thermal capacities of these are compared in a double calorimeter, being suspended one from each arm of a short beam balance. If their thermal capacities are not alike a calculated weight or copper wire is introduced into that of least thermal capacity. They are in this way brought to have the same thermal capacity, so that in an experiment on the empty spheres there is no effect on the balance.

One of these is now pumped full of air, and the specific heats of the spheres again compared. The weight of condensation now obtained is that due to the gas alone. It is evident that many sources of error obtaining in the former method are removed in the latter. The results obtained are also far more consistent one with another. In this case the specific heat is calculated directly on the formula given in my paper on the steam calorimeter:—

$$S = \frac{w\lambda}{W(t_2 - t_1)},$$

where λ is the latent heat of steam, w the weight of steam condensed by the gas, W the weight of gas, and t_2 t_1 the extremes of temperature obtaining. S so calculated may be subject to some slight corrections, which I will not here enter into.

Up to the present I have only dealt with air, but I have made preparations for resuming shortly my work, dealing with other gases, over critical temperatures, if possible, in some cases, and making confirmatory experiments on air and also in extension of those given below.

The spheres used are about 6·7 cm. internal diameter; volume 158·5 c.c. They weigh about 92·2 grms. That containing the air is tested hydraulically to 1000 lbs. per square inch.

* Read before the Royal Society, November 22nd, 1888.

† "On the Method of Condensation in Calorimetry" (by J. Joly), *Roy. Soc. Proc.*, vol. xli., p. 352; and "Ueber das Dampfcalorimeter" von R. Bunsen), *Wiedemann's Annalen*, vol. xxxi., p. 1.

TABLE I.

Weight of Air in the Sphere = 5·4816 grms.
Pressure at 100° C. about 27,700 m.m. of Mercury.

$$\text{Density} = \frac{W}{V} = 0\cdot03458.$$

No.	t_1 .	t_2 .	λ .	w .	Sp. heat.
1.	14°93	100°24	536°3	0°1536	0°17615
2.	16°52	100°17	536°4	0°1507	0°17629
3.	14°94	100°15	536°4	0°1547	0°17766
4.	16°28	100°15	536°4	0°1513	0°17653
5.	15°18	100°22	536°4	0°1550	0°17835
Mean					0°17699

TABLE II.

Weight of Air in the Sphere = 4°3084 grms.
Pressure at 100° C. about 21,800 m.m. of Mercury.

$$\text{Density} = \frac{W}{V} = 0\cdot027182.$$

No.	t_1 .	t_2 .	λ .	w .	Sp. heat.
1.	16°10	100°22	536°4	0°1194	0°17672
2.	15°20	100°33	536°3	0°1222	0°17868
3.	16°88	100°33	536°3	0°1182	0°17631
4.	15°20	100°15	536°4	0°1199	0°17572
5.	16°69	100°12	536°4	0°1188	0°17728
Mean					0°17694

TABLE III.

Weight of Air in Sphere = 3°1357 grms.
Pressure at 100° C. about 15,890 m.m. of Mercury.

$$\text{Density} = \frac{W}{V} = 0\cdot019784.$$

No.	t_1 .	t_2 .	λ .	w .	Sp. heat.
1.	15°88	100°07	536°5	1°0870	0°17680
2.	16°69	100°06	536°5	0°0853	0°17506
3.	16°43	100°04	536°5	0°0876	0°17926
Mean					0°17704

These, it is seen, afford a result above that theoretically assigned to air at constant volume (0°1684). They differ too somewhat from some experiments made by the first-described method, are somewhat lower than their mean, but the consistency displayed throughout in the thirteen experiments given, especially in Tables I. and II., leads me to give these numbers as probably a close approximation to the true value. One point is at any rate brought out clearly, that is, that the surmise that the specific heat of a gas at constant volume was a quantity independent of pressure—a surmise based partly on the constancy of the specific heat at constant pressure—would appear to be correct. The values in the three tables, calculated simply on the weights of gas dealt with in each set of experiments, show results quite independent of the great variations of pressure and density obtaining, the weight of condensation simply falling off with the decrease in the weight of gas, till in the third table w is beginning to feel the errors incidental to the considerable mass of the spheres and to give more variable results. I have prepared very thin light spheres with a view to continue the experiments to lower pressures with less danger of error.

The cause of the excess in the value obtained above the theoretical is not apparent, especially in view of the independence of pressure displayed. The experiments embodied in the three tables were made indeed upon the one sample of air—some being liberated after the first five experiments, and so on—but this had been dried through three calcium chloride tubes and two large U-tubes of phosphorus pentoxide before passing into the pump. Between the pump and the sphere it passed through a brass tube stuffed with asbestos which had been previously

heated to redness. The object of this is to guard against oil being carried from the pump into the sphere.

My first determination of the specific heat of air at constant volume was effected on the 13th of April of this present year. It was made by the method described in the beginning of this note at a pressure somewhat higher than that at which the experiments of Table I. were effected. This experiment gave as a result the specific heat of air to be 0.17565.

NOTE. OCTOBER 18.

Subsequent more extended experiments have shown me that this condition was not absolutely fulfilled. A small reduction of the values recorded for the specific heat of air is necessary on this account, but insufficient to effect any remarks made in this note. Successive experiments on the empty spheres, I may observe, are sufficiently consistent one with another to warrant the assumption that the values recorded by me are not probably affected to the extent of one per cent by errors on the calorific capacities of the spheres.

PRELIMINARY NOTE ON A SILICO-ORGANIC COMPOUND OF A NEW TYPE.*

By J. EMERSON REYNOLDS, M.D., F.R.S.,
Professor of Chemistry, University of Dublin.

THE subject of this note is a fine crystalline substance, and is the first well-defined compound yet known in which we have reason to believe that silicon is in direct and exclusive union with the nitrogen of amidic groups. Its analysis and mode of formation lead to the conclusion that it is *silicotetraphenylamide*,

This body is produced when silicon tetrabromide (or the tetrachloride) is added to excess of aniline, diluted with three or four volumes of benzene. Aniline hydrobromate (or hydrochlorate) is a secondary product of interaction and separates, being insoluble in benzene. If aniline be in excess throughout the operation, the whole of the halogen precipitates as aniline salt, and there remains in solution impure *silicotetraphenylamide*. If aniline be not in excess, a bromo-compound is obtained analogous to Harden's rather ill-defined chlorinated product.

Distillation from a water-bath readily removes benzene from the solution, and a liquid remains which solidifies after some time to a yellowish mass. The latter dissolves in warm carbon disulphide, leaving a residue containing some thiocarbonyl, and cautious evaporation of the solution leads to the separation of magnificent crystals of the silicon compound. These form chiefly at the surface of the liquid, as they are specifically lighter than the solution.

When twice re-crystallised from carbon disulphide, the substance is obtained in a state of purity.†

The crystals of *silicotetraphenylamide* are perfectly colourless short prisms of considerable size. They melt at 136–137° to a transparent liquid, which can be heated to 210° without decomposition. On cooling, this liquid solidifies to a transparent glass, which, like the original crystals, can be easily decomposed by water.

If *silicotetraphenylamide* be heated under diminished

pressure (about 80 m.m.), it affords a distillate of aniline, and leaves a residue which seems to be the silicon analogue of *carbodiphenylimide*; but the latter has not yet been completely analysed.

The detailed investigation of the new substance and its derivatives is in active progress, and promises to throw light on the hitherto obscure relations of silicon and nitrogen.

I have reason to believe that the homologues of aniline, and certain other analogous nitrogen compounds, act like excess of aniline on the silicon haloids, and produce substances similar to the subject of this note. These reactions are also being investigated in my laboratory.

NOTE ON THE DETERMINATION OF COPPER BY THE IODIDE PROCESS.

By ROWLAND WILLIAMS, F.I.C., F.C.S.

As there appears to be considerable difference of opinion concerning the value of the iodide process for the determination of copper—certain metallurgical chemists having raised objections to its use, while, on the other hand, Mr. Westmoreland regards it with great favour—I thought it worth while to try the method in estimating the percentage of copper in two samples of sheet copper which I recently had occasion to examine.

According to Sutton ("Volumetric Analysis," 4th Edition, p. 142), the iodide process is principally available for the rapid estimation of small quantities of copper, and the results are accurate in the absence of per-salts of iron and other reducible substances.

Fresenius, who, by the way, claims that the process was devised in his laboratory by De Haen, employs a sulphuric acid solution of the copper. Fresenius says ("Quantitative Analysis," 7th Edition, p. 259) the results are accurate if the copper solution be free from sesquioxide of iron, free nitric and hydrochloric acids, and other bodies which decompose iodide of potassium. He also remarks that the solution, after adding the potassium iodide, must not be allowed to stand too long before titration.

My estimations were made by dissolving 63 grains of each sample in the theoretical amount of dilute nitric acid, boiling off nitrous fumes, adding carbonate of soda solution until a slight permanent precipitate appeared, then acetic acid in slight excess, and making up to 10,000 grains. One-tenth of the whole (= 6.3 grains of the sample) was measured off for each titration, excess of potassium iodide added, and, after allowing to stand a few minutes, titrated with decinormal hyposulphite solution. This mode of procedure is essentially the same as that adopted by Mr. Westmoreland, excepting the strength of the hyposulphite solution, which, for convenience sake, I make decinormal.

When an aliquot portion equivalent to 6.3 grains of the sample is taken, and decinormal hyposulphite used, if the number of grains of hyposulphite employed in each titration be divided by ten, the percentage of copper is at once indicated. In the case of the two samples of copper under consideration, the iodide process yielded results very similar to those obtained by the method which I usually employ. The iodide process is undoubtedly both expeditious and accurate in the case of refined copper or pure copper solutions, but certain impurities, especially lead, iron, and arsenic, seem to exert a prejudicial effect. Ferric salts in particular invariably cause the results to be inaccurate. In his original paper on this subject (*Journal of the Society of Chemical Industry*, vol. v., p. 52), Mr. Westmoreland says he is inclined to think that ferric acetate liberates iodine from potassium iodide. I have proved by actual experiment that this is the case,

* Read before the Royal Society, Nov. 22, 1888.

† A large quantity was prepared in June last, and about 50 grms. of the pure compound were exhibited on September 11th in Section B during the meeting of the British Association at Bath.

and the same remark applies to ferric nitrate. Ferric acetate equal to one-tenth of a grain of iron, acting on potassium iodide solution acidified with acetic acid liberated 0.0508 grain of iodine in five minutes. Under the same conditions, ferric nitrate equal to one-tenth of a grain of iron liberated 0.0635 grain iodine. I also find that arsenic acid quickly decomposes potassium iodide to an estimable extent.

It may, of course, be argued that traces only of these impurities are likely to be present in liquids in which the copper is to be estimated by the iodide process, as the operator would have separated the copper in a fairly pure form, previous to titration. It is advisable, however, to call special attention to these possible sources of error.

Laboratory and Assay Office,
28, Pall Mall, Manchester.

WATER SUPPLY TO STEAM BOILERS.

By THOMAS T. P. BRUCE WARREN.

IT is a common practice to use waste steam for heating water before injecting into a boiler; in most cases the exhaust steam from the cylinder is condensed, and flows back again into the boiler. If the cylinder be lubricated with a compound oil containing a saponifiable oil or fat, serious consequences are likely to result, in consequence of "pitting" of the plates. Although this is so well known, I am not aware of any published statement on the chemistry of this subject.

A few years ago a sample of water drawn from a boiler was said to contain grease. Both the water and deposit from the boiler were repeatedly examined, with negative results. A sample of scum collected from the surface of the water was subsequently examined in the following way:—

A weighed quantity of the dried scum was digested in warm dilute HCl; the solution, on cooling, was coated with a dirty, unctuous film. On filtering and washing, the soluble matter was removed, the dried residue was treated with CS₂, which, on evaporation, yielded four per cent of a white solid fat, consisting principally of stearic acid.

As these earthy soaps float, they attach themselves to the boiler plates, and, being decomposed, leave a greasy spot on the plates. This grease prevents the water from coming in contact with the plate, which probably gets more strongly heated; however, the plates rapidly corrode at these spots, but how far the action is chemical or mechanical, or combined, it is not so easy to decide.

Petroleum or other non-saponifiable lubricators should be used in every case where it is intended to utilise waste steam, direct, in heating the feed water.

I brought this corrosion of boiler plates under the notice of the late Mr. Keats, Chemist to the Metropolitan Board of Works, who said that this corrosion was due to sulphate of lime. If sulphate of lime be present in this scum, the corrosion may be more easily explained, as the generation of sulphurous acid is by no means improbable.

Chloride of magnesium, if present in large quantity in a feed water, will generate HCl, and which, escaping with the steam, will rapidly corrode the iron pipes conveying the steam. A water residuum heated to 260° F., evolves large quantities of HCl, if much chloride of magnesium be present. Probably the reason why this corrosion is not perceptible with marine boilers is because the steam pipes are made of copper.

The Decomposition of the Haloid Salts of Silver under the Influence of Light.—F. Griveaux.—The decomposition of the haloid silver salts occasioned by light may be considered as a dissociation similar to that produced by heat.—*Comptes Rendus*, Vol. cvii, No. 21.

NOTE ON ERYTHROXYLON COCA GROWN IN INDIA.

By C. J. H. WARDEN, M.D., F.R.C.S.

(Concluded from p. 262.)

THE next point I propose referring to in connection with this enquiry is the apparent influence of cultivation and locality on the yield of alkaloid. For convenience of reference I have tabulated all the available information on the subject of cultivation in Table No. VI.

In Table No. VII. I have arranged the data regarding height above sea level, and average rainfall of the districts in which the samples were grown.

The various samples of coca leaf examined during the course of my experiments were thus grown under different methods of cultivation and climatic influences, and it will be of interest now to compare these conditions with those under which the plant grows in Bolivia, a district which is stated to produce the best leaves. Two articles have appeared by Drs. Squibb and Rusby respectively (*Pharm. Journ.*, 1885), which deal with the cultivation of the coca plant. Rusby for more than two months was continuously engaged in the study of the coca plant and its products in the districts of Bolivia. The district of Caracota may be considered fitly representing the remainder of Youngos, and Youngos as representing the principal coca districts of the republic. The first coca plantations are found at an altitude of 6400 feet, and after passing the 2000 feet level there are few, if any; and within this four to five thousand feet lie the cocales of Bolivia. The soil is very diversified, ranging from a very light decomposed shale or sandstone to a heavy blue or chiefly yellow clay. The rainy season begins in October and continues until May or June, during which period the rains are copious and almost constant. During the succeeding two months there is scarcely a drop of rain, and during the next two there are only occasional showers. By the natives the leaves are classed as sweet and bitter leaves. The sweet leaves contain an abundance of alkaloids other than cocaine; but usually contain a large percentage also of cocaine. In the sweet leaves the bitter taste of the cocaine is marked by the presence of the other alkaloids, while in the bitter leaves the taste of cocaine is predominant. It would appear that the percentage of sweet alkaloids varies inversely as the amount and continuousness of moisture the plant receives. From a high altitude, the best results as to total alkaloids have been yielded by plants grown on a hill side soil rich in vegetable manure. But a rivalry exists between this variety of soil and a yellow clay; the author is inclined to think that those who prefer the latter soil do so because it yields a somewhat larger crop.

The ground for the nursery beds is prepared during the latter part of the dry season by breaking it up very thoroughly to the depth of a foot or more. The plan of sowing the seeds broadcast as soon as gathered, and covering with a little earth, or better, a layer of banana leaves or decaying vegetable matter, has been found to answer: germination requires from eight to twelve days longer than by adopting the native method, which consists in depositing the seeds as soon as gathered in a shaded place in layers an inch or more deep, and covered with a thin layer of decaying leaves. The heat generated by the decomposition of the fleshy pericarps seems to induce germination, and the embryo bursts its bony covering. This growth unites them in from eight to fourteen days into a solid mass, which is broken up into small pieces and planted in furrows in the nursery. In this process very many of the sprouts are broken off and the plants destroyed. A covering of brush or straw must be placed over the nursery, at first only 3 or 4 inches above the surface, and elevated as the plants grow.

On the manner in which the ground is prepared for the plantation much of the future well-being of the plant depends. The ground should be thoroughly powdered to

TABLE NO. VI.

Source of leaves.	Per cent of alkaloid on anhydrous leaves.	Method of cultivation.
Central Terai Tea Co., Darjeeling ..	1'115	Seedlings received from Society in 1885; grown in Bungalow compound and receiving a slight forking by coolies. Soil, black loam; no manure used.
Matelli Tea Garden, Jalpaiguri ..	1'022	Seedlings from Society; about 18 months old. Virgin forest land, black on top, sandy underneath. Plants not specially treated.
Arcuttipore Tea Co., Cachar	1'369 1'671	Seedlings from Society; age about 19 months. Soil, sandy loam; vacancies in an old tea clearance; manured with old cow-dung and top dressed with soot.
Chulsa, Jalpaiguri Dooars	0'610	Seedlings from Society, 1887; planted out 4 feet x 4 feet in virgin forest; chocolate-coloured leaf-mould.
Jaunpore District	0'571	Seedlings from Society; about 2 years. Old sandy loam garden soil, highly manured.
Ranchi	1'069 0'811	Seeds from Paris; plants two years old. Planted 2' x 2'. Soil, loam with much iron in it, of a chocolate colour; once manured with cow-dung.
Society's Gardens, Alipore, Calcutta	0'358 0'973	Seedlings of various ages, from 6 months to 2 years; some in pots and some planted in ordinary garden soil.

TABLE NO. VII.

Districts.	Per cent of alkaloid on anhydrous leaves.	Height above sea level. Feet.	Average rainfall. Inches.
Central Terai Tea Co., Darjeeling..	1'115	About 900.	—
Matelli Tea Co., Jalpaiguri	1'022	About 1700.	About 180.
Arcuttipore Tea Co., Cachar	1'369 1'671	About 120.	Av. of six years, 129.
Chulsa, Jalpaiguri Dooars	0'610	2200.	180 to 200.
Jaunpore Districts	0'571	300.	30 to 40.
Ranchi	{ 1'069 0'811 }	2200.	About 65.
Society's Gardens, Calcutta	{ 0'358 0'973 }	—	About 66.

the depth of two or, if possible, three feet, and all roots and large stones removed. It is generally believed that shade tends to the production of the best quality of leaves, and the cocales are therefore planted thickly with a small broad topped leguminous tree related to the St. John's head plant. The custom appears to have arisen from two considerations. There is a period already referred to of two or three months during which no rain falls, and then these trees afford protection from the sun. Secondly, because shade conduces to the production of a large smooth leaf of elegant colour, and thus adds to the appearance of the product. From repeated comparative assays made by Rusby, of shade and sun grown leaves from adjoining plants, the sun grown leaves were invariably much richer in total alkaloids.

The plants are transplanted from the nursery at the advent of the permanent rains, and are set out from half an inch to three feet apart. They grow to a height of 2 to 6 feet, but the largest plants do not yield the best leaves. Great care must be taken to keep the soil thoroughly stirred and free from weeds. The first picking of leaves is made one year and a half from the date of transplanting, or two and a half from the date of sowing the seeds.

The chief danger of picking the leaves earlier than the period mentioned, is not the strain upon the vitality of the young plants, but because it is almost impossible to avoid breaking off the very tender tips of the twigs, the result being fatal to many plants.

During the first few years the percentage of alkaloids increases rapidly, reaching its maximum at or before the tenth year; at the age of twenty it begins to diminish, but with extreme slowness, so that plants are practically in their prime up to the age of thirty-five or forty. The

decline is then probably due rather to exhaustion of the soil than of vitality of the plant. Fertilisation of the soil has never been tried, but it appears probable that as much could be done for the coca in this way as has been done for other plants.

The time of picking is determined solely by the condition of the leaves. When mature they turn yellow if in the dry season, and brown if in the rainy, and within eight days at the outside will fall if not plucked. No irrigation is resorted to during the dry season. Rusby is of opinion that though it is possible that irrigation might increase the size of the crop, yet, that after a long time, an abundant and steady supply of water would result in a decrease in the amount of alkaloids. Moist seasons produce the most delicate leaves of finest quality, while droughts are very destructive to the crops. Each bush, as a rule, yields three crops a year; or in exceptional localities, four crops.

After plucking, the leaves are exposed to a hot sun upon a pavement of well-fitted flat stones, and stirred occasionally until dry. Under favourable conditions the drying is accomplished in about three hours. A few drops of rain are sufficient to decolourise and ruin the sale of the coca, though Rusby thinks it probable that such decolourisation, if produced by little rain, does not necessarily indicate loss of alkaloid. After drying, the leaves are placed in storage sheds, when the leaf undergoes a slight sweating process.

As far as one can judge from the data available, altitude in India does not appear to have much, if any, effect on the percentage of alkaloid present in the coca leaf. Taking two extreme cases, the coca grown on the Matelli Tea Co.'s garden, Jalpaiguri, at an elevation of 1700 feet, yielded 1'022 per cent of alkaloids, while that grown at Arcuttipore in Cachar, at an elevation of only 120 feet, yielded from 1'3 to 1'6 per cent of alkaloid. Again, the amount of rainfall does not appear to have been a factor of any moment, for we have the coca grown in the Jaunpore District, with a rainfall of 30 to 40 inches, yielding only four-hundredths per cent less alkaloid than that yielded by the leaf grown at Chulsa in the Dooars, with a rainfall of from 180 to 200 inches. As Rusby points out, the plants must not only have an abundant supply of water at the roots, they must be bathed in a humid atmosphere for the greater portion of the year. In considering these questions, however, of altitude and climatic influences on the alkaloid contents of the leaf, it must be remembered that in order to make the results strictly comparable, the age of the plants and the condition of the leaf as regards maturity at the time it was plucked, should be similar in all cases. But the samples examined by me were picked at different periods; thus the Matelli,

and Central Terai Tea Co.'s leaf was plucked in July, the Chulsa and Jalpaiguri in October, the Arcuttipore twice a month since 18th May, 1887. Extreme caution is therefore requisite in drawing deductions as to the special adaptability of any particular district for the growth of coca. The necessity for this caution is well seen in the results of the examination of the samples grown in the Society's Gardens, Alipore. The first sample yielded only 0.358 per cent of total alkaloid, while the second, examined about six weeks later, contained 0.973 per cent of alkaloid, a difference of nearly 300 per cent.

As regards the effects of cultivation and manure on the yield of alkaloid, it would appear from the reports I have received that in only two of the districts was the soil specially manured. At Arcuttipore the manure consisted of old cow-dung, with a top dressing of soot. In the Jaunpore district the soil is stated to have been highly manured, but no particulars as to the precise nature of the fertiliser are afforded. The leaf grown at Arcuttipore yielded very considerably more alkaloid than any of the other samples examined; while that grown in the Jaunpore district contained only 0.571 per cent of alkaloid. I have no information whether the Arcuttipore plants were grown in the shade or open. On the Jaunpore Tea Estate there appear to be four plants, two in full sunshine, and measuring 5½ feet and 5 feet 2 inches in height respectively; one in partial shade 3 feet high, and one in shade 5 feet high; and I gather from the Manager's letter that the leaf sent me was collected from the plant which grew in the shade.

Taking into consideration the amount of potash contained in the leaves, and the rapid exhaustion of the soil which would necessarily ensue from repeated plucking of the leaves, it appears to me that, though at first a nitrogenous fertiliser would be beneficial, yet after a time the addition of a fertiliser containing potash in some form, in addition to the nitrogenous matter, would be necessary. The amount of nitrogen in the soot and cow-dung might possibly suffice, but whether the amount of potash in the cow-dung would be sufficient to supply the place of that removed from the soil by the leaves is an open question.

The method of drying the leaves by artificial heat instead of in the direct rays of the sun, does not appear to me objectionable. The object, which should, I think, be kept prominently in view, is to dry the leaves as thoroughly and quickly as possible at the lowest temperature. The plan adopted at Arcuttipore of first withering the leaves in the shade and then drying them in a tea dryer at 150° F. for ten minutes, appears to me as good as any. I do not think any advantage is to be gained by employing a higher temperature. In whatever way dried the leaves should be at once packed in air-tight boxes *directly they are cold*. Dried leaves exposed to air rapidly absorb moisture, and a few hours' exposure in a damp day will indicate in the leaf 18 to 20 per cent of moisture.

The amount of leaf yielded by a plant obviously varies with its age. At Arcuttipore, with plants about 19 months old, the Manager writing in August, 1887, states, that the leaf has been collected twice a month since 18th May last: the quantity of green leaf obtained at each plucking from nine plants varied from ¾ to 1 lb.; one pound of green leaf yielding about 3½ ounces of finished coca. At Chulsa, Jalpaiguri, 143 plants yielded 3 lbs. of dry leaf.

The apparent peculiarity of the alkaloid extracted from Indian grown coca leaves of not forming spontaneously crystallisable salts on evaporation of aqueous and other solutions, raises the question of the value of the drug for therapeutic purposes. In the manufacture of hydrochlorate of cocaine, the solution of the alkaloid in hydrochloric acid is evaporated at a low temperature with constant stirring, until the solid salt ceases to lose weight. Solutions of hydrochlorate of cocaine prepared from Indian grown coca leaves treated in a similar way, also yields a solid hydrochlorate. The physiological action of the hydrochlorate so prepared in numbing the tongue was very marked, but it seemed to me that it would be more

satisfactory to have the opinion of a medical man on the suitability of the drug for therapeutic purposes. Hydrochlorate of cocaine in a four per cent aqueous solution is employed in ophthalmic practice. I accordingly prepared a solution of that strength, which I submitted to Dr. Saunders, Professor of Ophthalmic Surgery at the Medical College, Calcutta, for report. Dr. Saunders has tried the effects of the drug on patients, and has very kindly favoured me with the following note of its action.

"I have used the solution of cocaine sent by you in some 13 operations for cataract, and many minor operations upon the eye: I find no difference in its physiological effect from other cocaine, except that it appears to have a quicker and a slightly stronger action. As an anæsthetic upon the eye it is perfect."

There can thus be no question regarding the activity of the alkaloid obtained from Indian coca. On purely pharmaceutical grounds the use of cocaine obtained from Indian coca might be objected to, as it does not apparently form spontaneously crystallisable salts, but as the salts of cocaine are, as a rule, used in solution, this objection cannot carry much weight. The percentage of alkaloid contained in samples of the Indian grown drug exceeds considerably the amount stated to have been found in any of the published assays of coca leaf which I have had an opportunity of seeing; and I think it not unlikely, that as the Indian plants—now in their infancy—mature, still larger percentages of alkaloid will be found in the leaves.

Thus, though the suitability of India for growing coca is clearly established, the point whether it will be commercially successful or not to grow the drug there is another question. The present sources of coca are very large: according to Squibb (*Ephemeris*, May, 1887), the Peruvian Government is said to record and tax a production of over 15,000,000 pounds per annum, and the Bolivian Government about 7,500,000 pounds; of this latter quantity about 55 per cent is consumed in Bolivia, Argentine Republic and Chili each 14 per cent, and Peru 10 per cent, while the remaining 5 per cent is exported to the United States and Europe, thus giving about 375,000 pound as the export of Bolivia. As Peru produces about double the quantity credited to Bolivia it seems probable that about double the quantity may be exported, or 750,000 pounds, and if this, too, goes to the United States and Europe it would make an aggregate of about 1,125,000 pounds annually. Squibb pertinently remarks that 1,000,000 pounds of coca leaf would yield at least 2500 pounds of cocaine, while one-fourth of that quantity would probably overstock the whole world. Probably small parcels of Indian coca leaf would find a ready sale in Europe at good prices, but to plant out large areas would, I think, be a hazardous experiment. For it must be remembered that the uses of coca are very limited in Europe, the drug being almost solely used as a medicine, and, as far as one can judge, there is little or no chance of coca preparations ever coming into general use, for example, as beverages. The question of the synthesis of cocaine, enabling the drug to be prepared artificially on a large scale, is also a not very remote contingency, for work has already been done in that direction by Merck and others.

(In the "Report on the Botanical Gardens, Nilgiris, for 1884-5," the Superintendent remarks:—"Last winter this alkaloid is said to have fetched 2s. 6d. per grain. At this price, could it have been maintained, its cultivation would have been productive of enormous profits, but the price has since declined to 7d. per grain, and it is very unlikely that even this sum will be realised much longer. In this opinion Mr. Thiselton Dyer concurs, and he moreover wrote a short time ago to caution me against being too sanguine that the cultivation of coca would be a commercial success, or advising me at any rate to discount very largely the reports which had been spread abroad about it.")

In conclusion, it only remains for me to express my thanks to Mr. Blechynden, Secretary to the Society, for

the trouble he has taken not only in collecting samples of coca from the various districts, but in supplying me with information relative to local methods of cultivation.

EXPERIMENTS UPON ALUM BAKING-POWDERS, AND THE EFFECTS UPON DIGESTION OF THE RESIDUES LEFT THEREFROM IN BREAD.

By Prof. J. W. MALLET, University of Virginia.

It has been almost universally conceded that alum itself, when added singly to bread or other food, is positively injurious to health, and that its use, even in the small proportion sometimes employed to improve the appearance of bread made from unsound or inferior flour, must be regarded as reprehensible. But since the extensive introduction, in the United States, of baking-powders made with alum and bicarbonate of soda, there has been much dispute as to the harmlessness or harmfulness of the substances which are left in bread made with such powders after the mutual reaction of their constituents and the completion of the baking process.

It has been claimed by those who advocate the use of cheap baking-powders made with alum as one of the ingredients, that as soon as the mixture of alum (usually first deprived by heating of the whole or much the greater part of its water of crystallisation—so-called "burnt alum") and bicarbonate of soda is moistened, as in working it up with flour and water to form dough or "sponge," the aluminum sulphate is decomposed, sodium sulphate being formed, with which there also remains sulphate of ammonium or potassium, as ammonia or potash alum has been used, and the aluminum assumes the form of aluminum hydroxide, insoluble in water, and therefore supposed to be inert and harmless in the stomach and alimentary canal. It has been noticed that the aluminum is also partly converted into phosphate in presence of the phosphates naturally occurring in flour, and this has been also taken to be insoluble and inert. It has been further claimed that at the temperature of the baking oven aluminum hydroxide is itself decomposed, water being given off, and the highly insoluble aluminum oxide, or alumina, left behind, to be discharged from the intestines as might be so much clay or other harmless and indifferent matter.

On the other hand, it has been asserted, by some of those who oppose the use of alum in baking-powders, that the decomposition is not, or may not be, complete, and in any case that, as all of the constituents of the alum remain in the bread, the action upon the human system must be essentially the same as if the alum itself remained intact.

In the discussion of the effects on health of the residual substances left in bread made with alum baking-powders, there has been a good deal of loose argument, based upon data which were either merely assumed as probable or were too imperfectly supported by actual experiment. In such experiments as have been hitherto recorded, bearing directly on the question, there are many points left in an indeterminate state, and calling for further investigation in order to clear them up and admit of an impartial conclusion being reached. The following work was undertaken with a view to furnish some more exact and satisfactory evidence of the kind required for the purpose of reaching such a conclusion.

1. General Nature of the Baking-powders Examined.

Of these there were 27 samples, representing 17 different brands. It was thought desirable to examine, at least in some cases, several samples of the same brand, in order to form an idea of the degree of uniformity to be counted upon as presented by the product of the same manufacturer.

The samples were in unbroken original packages, as found in ordinary retail trade. A good deal of difficulty was experienced at first in procuring samples of some of the brands, until it was observed that not in the larger and better shops of the principal cities, but in smaller shops and more obscure streets and towns, were these to be met with, indicating sale chiefly among the poorer classes.

Nearly all of these powders contained as their acid ingredient a mixture of alum and acid phosphate of calcium ("superphosphate"). In but one case was alum alone found. The alum employed was, for the most part, made with ammonium, not potassium sulphate, although the latter salt was also met with either singly or mixed with the former.

All contained as the alkaline ingredient acid carbonate of sodium ("bicarbonate of soda"). All contained starch, or, in two or three instances, crude flour or starch imperfectly separated from gluten.

2. Amount of Carbon Dioxide (Carbonic Acid) Gas given off on Moistening each Baking-powder with Water.

As the object of using a baking-powder in making bread is to produce porosity, by the liberation and expansion of gas-bubbles uniformly distributed through the mass, the amount of gas set free from a given quantity of the powder by moistening it is obviously an important point to be determined.

This amount was found to be very variable on testing carefully under similar conditions the different samples examined. Reducing the volume of gas to the same standard temperature and pressure, and allowing for gas retained in solution by water at the temperature of each experiment, the smallest quantity obtained was 36.91 cubic inches from one avoirdupois ounce of baking-powder. The average for all the samples was 66.00 cubic inches from the same weight of powder. The largest quantity obtained was 99.37 cubic inches. Hence, if the average result be taken as the standard of comparison, a departure from it of as much as 44 per cent in defect and 50 per cent in excess was observed.

In obtaining these results no account was taken of any ammonium carbonate, which is employed, when at all, only in quite small proportion; this would only assume the gaseous form under the influence of the heat in baking.

The variability observed appears to be partly due to variation in the proportion of starch or other indifferent matter used, partly to the variable character of the commercial bicarbonate of soda employed (containing a larger or smaller proportion of true bicarbonate), partly to greater or less purity of the other active ingredients, partly to greater or less care in the adjustment to each other in proper proportions of the acid ingredients and the soda, partly to want of due care to insure uniform mixture of the ingredients, but mainly to greater or less absorption of moisture from the air in keeping, different degrees of care in drying the materials, and in putting up the powder in packages for sale, and no doubt difference in age of some of the samples.

3. Relation of the Variable Product of Carbon Dioxide Gas to the Amount of Powder necessary to be used in making Bread.

Aside from the bearing on the fitness for producing porosity in bread, and hence on the money value of a baking-powder, of the amount of carbonic acid gas given off by a given quantity of the powder, there is to be considered the bearing upon health of the habitual use of more or less of the powder to produce the same effect in "raising" bread. The directions accompanying most of the brands call for two teaspoonfuls, or in some cases two or three teaspoonfuls, for each quart of flour; but it may be safely assumed that in actual practice the bread-maker will take such a quantity as experience may show to be necessary to produce the desired "lightness," whether by varying the number of spoonfuls recommended,

or by changing the extent of filling of the spoon, or by discarding this measure in favour of some other the use of which is guided by observation of the resulting bread. Hence the use of a poor baking-powder, or one in poor condition, yielding but a small proportion of gas, will lead to the employment of a relatively larger quantity, and will cause a larger amount of residual matter to be left in the same quantity of bread, causing increased ill-effect upon health if such residual matter be injurious at all.

This point is to be borne in mind in forming any estimate of the quantity of residue from a baking-powder which any single consumer of bread made with it may have to encounter.

4. *Nature of the Ingredients in a Solution obtained by Treating the Several Baking-powders with Water, so far as Excess of Acid or Alkali derived from the Powder is Concerned.*

On acting with a definite excess of cold water upon each sample examined, and filtering off the solution after escape of gas has ceased, leaving on the filter the starch and insoluble mineral products of the chemical action which had taken place, the clear liquid was examined as to its reaction to test-paper, and the excess of acid or alkali was carefully determined.

In nearly all cases the liquid was alkaline, and the excess of alkali present was found equivalent to an amount of bicarbonate of soda varying from 2.06 to 19.11 grains for each ounce avoirdupois of baking-powder used.

In two cases the reaction was acid, and to an extent which, if the excess be counted as alum over and above that required to neutralise the soda present, would be equivalent in the one case to 0.86 grain, and in the other case to 3.14 grains of burnt ammonia alum (or to 1.58 grains and 5.78 grains of crystallised ammonia alum respectively) per ounce of baking-powder. In fact, these two baking-powders, being made with alum and acid calcium phosphate, the acidity was in part due to excess of the latter salt, though a soluble compound of aluminum was also present.

These results indicate the degree of variation in the adjustment to one another of the acid ingredients and the bicarbonate of soda, more or less carelessness as to the purity, and therefore real chemical efficiency of the two classes of material, especially, in all probability, as to the relative proportions of true bicarbonate of soda, of the neutral carbonate, and of moisture in the soda used, and more or less inaccuracy in the weighing out, and want of uniformity in the mixing of the materials as taken.

5. *Examination of the Watery Solution from the Several Baking-powders as to the Presence therein of Aluminum and Calcium.*

It has been commonly claimed, in defence of baking-powders made with alum, that, conceding this salt to be itself injurious, it is decomposed in acting upon the bicarbonate of soda, assuming the alkaline material to be used in sufficient amount, hydroxide (or hydrate) of aluminium being formed, and that the latter is quite insoluble, and hence inert physiologically, so that no harm can result from its presence in the digestive organs. It has usually also been assumed that the calcium of calcium acid phosphate is rendered insoluble by conversion into tribasic phosphate on reaction with a sufficient amount of bicarbonate of soda.

On examining, however, the solutions obtained by acting with water on the various baking-powders examined, due care being taken to remove any silica, to decompose any phosphate present, and to fully identify the aluminum and calcium found, it appeared that these solutions in all cases (except a single brand, made with alum alone without phosphate, in which there was but a trace of calcium) contained both aluminum and calcium, in relatively small quantity it is true, but in some cases to an extent equivalent to as much as 4.19 grains of burnt or 7.72 grains of

crystallised ammonia alum, and to as much as 3.15 grains of lime per ounce of baking-powder. Hence it is not true that the aluminum and calcium are left in a condition wholly insoluble in water; at any rate, in the presence of the other residual material of the baking-powder.

In the powders containing calcium acid phosphate along with alum, part of the lime is in solution as carbonate dissolved by excess of carbonic acid. In such of these phosphate and alum powders as had least excess of alkali (bicarbonate of soda), the whole, or nearly the whole, of the phosphoric acid was left in the part of the residue insoluble in water.

6. *Presence of a little Organic Matter (Soluble Starch) in the Watery Solution obtained from the Baking-powders.*

The solution obtained by acting on the powders with excess of cold water gave a strongly-marked violet tint with a weak solution of free iodine, due to the presence of a little soluble starch. No dextrose or glucose was found. The presence of organic matter, although in very small amount, may possibly aid in bringing a little aluminum, or calcium phosphate, or aluminum hydroxide, into solution.

7. *Existence of Aluminum largely as Phosphate in Consequence of the Use of Calcium Acid Phosphate along with Alum.*

It has been pretty generally assumed that from alum baking-powders the aluminum is left mainly as hydroxide (hydrate) in the bread, though attention has been drawn to the fact that some aluminum phosphate may be expected to be formed from the phosphates of the flour itself. The quantity of aluminum phosphate so produced would probably be small. But, so far as the samples now reported on may be taken to represent the usual character of the alum baking-powders at present in the market, it will have been seen that nearly all of them are made with both alum and calcium acid phosphate, and in the reaction of these two ingredients on each other we have a source of the much more abundant production of aluminum phosphate. In fact, in all the powders of this mixed character examined, nearly the whole of the aluminum was present as phosphate after treatment of the powder with water. Not quite the whole, however, as in two or three cases aluminum was detectable in the watery solution, while the phosphoric acid was left altogether in the insoluble residue. Of course, in such baking-powders as are made with alum alone (no phosphate), the aluminum is left mainly as hydroxide.

8. *Presence of Iron in Small but Varying Amount in the Baking-powders Examined.*

Although the quantity of iron in any of the samples examined must have been quite small, and no special attention was given to its determination, it was incidentally observed that this impurity varied very notably from one sample to another. This seems to indicate very different degrees of pains taken by different manufacturers to procure and use pure materials.

9. *Determination of the Temperature to which the Interior of Bread is Subjected in the Process of Baking.*

As aluminum hydroxide and aluminum phosphate are heated they give off water, and in consequence of this loss of water they become less soluble in acids, the anhydrous aluminum oxide (or alumina) being practically altogether insoluble in diluted or even pretty strong acids, while the anhydrous phosphate can be dissolved by them only slowly and with difficulty. When, therefore, we come to consider the solubility or insolubility of the residues left in bread from alum baking-powders, not in water, but in the digestive fluids, especially in the acid gastric juice, it is important to know in what condition of hydration these residues are left in the bread, i.e., how far water has already been driven off and insolubility produced, and as a first step we need to know to what temperature the in-

terior of the bread has been exposed in the oven during baking.

There is ample information to be found as to the usual or desirable temperature of the oven, but I have found no results of direct experiments on the temperature attained by the interior portions of the bread itself. It is remarked by some writers that, as there is much water still left in the bread when the baking is complete, the temperature of the inside of a loaf cannot be expected to much, if at all, exceed the boiling-point of water under common atmospheric pressure. But it seemed desirable to make some direct observations on this point, and this has now been done; the temperature of the oven, and of the interior of the bread while baking, and up to the time of withdrawal, having been noted—1st, For a large public baking-oven of brick, 12 feet by 14 feet, heated by a coke fire; 2nd, For a smaller brick oven in family use; and 3rd, For the ovens of ordinary cast-iron cooking stoves burning wood and coal respectively. The results were substantially uniform. The temperature of the oven atmosphere varied from 472° to 496° F., while the maximum temperature shown by a registering thermometer with its bulb in the centre of a larger or smaller loaf of bread, ranged from 197° to 212° F., never exceeding the latter point. In the case of the lowest temperature noted the bread as taken out of the oven was not quite sufficiently baked through, retaining rather more than a proper amount of moisture in the centre of the loaf. Hence it may fairly be concluded, as the result of direct experiment, that the aluminum hydroxide and hydrated aluminum phosphate left in bread from alum baking-powders are never exposed in baking to a temperature higher than 212° F.

10. Determination of the Condition of Hydration of Aluminum Hydroxide and Hydrated Aluminum Phosphate after Drying at 212° F.

These two substances were prepared in a pure state by precipitation, carefully washed, and allowed, in the first instance, to become dry at the common temperature of the atmosphere, covering them lightly to exclude dust. A portion of each, contained in a small "boat," was then exposed in a wide tube, maintained at or close to 212° F. by an outside bath of water kept boiling, to a slow current of air nearly saturated with moisture at the same temperature, so as to place the material experimented on as nearly as possible in the same condition as if it were enclosed in a mass of bread undergoing the process of baking. This state of things was maintained for an hour and a half—a time considerably longer than that usually occupied in baking. The boat was withdrawn from the tube and accurately weighed, then heated gradually to bright redness, cooled, and weighed a second time. The difference between the results of the two weighings gave the amount of water removable from the material taken as in the condition in which it would exist in baked bread. The results were as follows:—

Aluminum hydroxide, as taken,	gave off	39.11%	water.
" phosphate, "	" "	31.65	"

These figures correspond to about one molecule of surplus water for each three or four molecules of the normal aluminum hydroxide ($\text{Al}(\text{HO})_3$), and a little over three molecules of water for each molecule of normal aluminum phosphate (AlPO_4).

11. Experiments upon the Influence on Digestion of Moderate Doses of Aluminum Hydroxide and Aluminum Phosphate Swallowed shortly before or along with Food.

Having been interested by the results of a few experiments made in my own person a year or two ago on the apparent interference with digestion of these substances, I have tried a larger number of such experiments under

more carefully noted conditions and with definite quantities of the materials used, in order to test directly the physiological effect of the residues from alum baking-powders, so far as this can be determined by their action in the case of a single person.

The experiments were made with a carefully prepared stock of the pure hydroxide and phosphate of aluminum, dried at 212° F., in the way and to the extent described above (10). A weighed quantity of one or the other was swallowed, either before—generally about ten minutes or a quarter of an hour before—a regular meal (using only a little water with the powder) or along with the food of an ordinary meal, and the effect, if any, upon the course of digestion noted and recorded. The experiments were made with intervals of three or four days between them; the food taken was of various kinds, but always simple and wholesome, and not likely of itself to produce disturbance of digestion; there was no pre-existing derangement of the digestive functions when any experiment was undertaken; as much care as possible was taken to avoid any mere fancying of expected symptoms, and to state with moderation what was actually experienced. The results of all the experiments made were recorded, and the record was preserved in the words which seemed at the time most accurately to express the sensations observed.

While on two or three occasions, particularly with the smallest doses used, there was no clearly observable effect, the general tenor of the experiments seemed to establish beyond doubt on my part the fact that the ingestion of the aluminum compounds used produced an inhibitory effect on gastric digestion, while in some cases, particularly with the larger doses, and on the whole rather with the hydroxide than the phosphate for equal weights of the two, the interference with the course of digestion was very notable. There was no gastric pain, nor were there any other symptoms of gastric or intestinal irritation, but simply the well-known oppressive sensations of indigestion properly so called, lasting for a longer or shorter time, but generally for at least two or three hours after the taking of food.

The quantity of aluminum hydroxide swallowed in each experiment varied from 10 to 50 grains, the average for all the experiments being about 28 grains. The quantity of aluminum phosphate used ranged from 10 to 100 grains, the average being 45 grains. These doses were intentionally made larger than the quantities of the aluminum compounds in question derivable from such an amount of bread as would usually be eaten at a time if alum baking-powder in anything like usual proportion had been employed in making it. The object was to ascertain with what doses distinct effects were noticeable, and this seemed to be generally the case with any dose not less than 20 grains of the hydroxide or with not less than 30 or 40 grains of the phosphate. It may, of course, be reasonably supposed that a considerably less quantity than would be necessary to produce decided discomfort when once administered might prove objectionable and injurious if habitually taken as a part of the bread of each daily meal. With the proportion of alum in most of the baking-powders in use, with the allowance of two teaspoonfuls (counted as about 200 grains, though as much as 250 grains was found to be sometimes measured by a cook) of powder to a quart of flour, and assuming 35 or 40 per cent of water in baked bread, a pound of bread would contain about 13 or 14 grains of aluminum hydroxide if alum alone were used in making the powder, or about 20 or 21 grains of aluminum phosphate if alum and calcium acid phosphate were used together, and all the aluminum were left in the bread as phosphate—these weights being taken for the substances assumed in the condition of hydration shown by the experiments recorded in preceding paragraphs.

(To be continued).

PROCEEDINGS OF SOCIETIES.

THE ROYAL SOCIETY.

THE Anniversary Meeting of this Society was held on Friday, November 30th, at Burlington House. The President (Professor Stokes) having delivered the anniversary address, the medals were presented as follows:—The Copley Medal to Professor Thomas Henry Huxley for his investigations on the morphology and histology of vertebrate and invertebrate animals; the Davy Medal to Mr. William Crookes, for his investigations on the behaviour of substances under the influence of the electric discharge in a high vacuum; the Rumford Medal to Professor Pietro Tacchini, for his investigations on the physics of the sun; a Royal Medal to Sir Ferdinand von Müller, for his investigations of the flora of Australia; and a Royal Medal to Professor Osborne Reynolds, for his investigations in mathematical and experimental physics. The Society next proceeded to elect the officers and Council for the ensuing year.

President—Prof. George Gabriel Stokes, M.A., D.C.L., LL.D.

Treasurer—John Evans, D.C.L., LL.D.

Secretaries—Prof. Michael Foster, M.A., M.D.; the Lord Rayleigh, M.A., D.C.L.

Foreign Secretary—Prof. Alexander William Williamson, LL.D.

Other Members of the Council—Prof. Henry Edward Armstrong, Ph.D.; Henry Bowman Brady, F.G.S.; Charles Baron Clarke, M.A.; William Huggins, D.C.L.; John Whitaker Hulke, F.R.C.S.; Prof. John W. Judd, F.G.S.; Edward Emanuel Klein, M.D.; Prof. E. Ray Lankester, M.A.; Prof. Herbert McLeod, F.I.C.; Sir James Paget, Bart., D.C.L.; William Pole, Mus. Doc.; William Henry Preece, M.I.C.E.; Sir Henry E. Roscoe, D.C.L.; Edward John Routh, D.Sc.; Prof. Arthur William Rücker, M.A.; and William James Lloyd Wharton, Capt. R.N.

In the evening the Fellows and their guests dined together at Willis's Rooms. In returning thanks for the health of "The Medallists," Mr. Crookes said:—

In the absence of Professor Huxley, who unfortunately is unable to be present this evening, I have been asked by our President to return thanks for the Medallists.

The Professor, in whose shoes I now stand, has lately put it on record that for twenty years he never rose to make a speech without his tongue cleaving to the roof of his mouth through sheer nervousness. I, on whom his duties have fallen, but, alas! not his mantle, crave your indulgence if I show that nervousness for which I can quote so excellent an authority, and beg you to bear with me patiently in what must be as great a disappointment to you as it is to myself.

Although I feel it embarrassing to take the place of a philosopher so renowned as Huxley, I am bound to say that even he cannot receive the Copley Medal—the ancient olive crown of the Royal Society, as it was called by Sir Humphry Davy—without regarding it as the culminating honour of his scientific career. I am also bound to say that the award of this Medal to such a man as Huxley confers at least as much honour on the Royal Society as on its renowned Professor.

As regards the other recipients of the Medals, Professor Tacchini the Rumford Medallist, Sir Ferdinand von Müller and Professor Osborne Reynolds the Royal Medallists,—co-workers with myself in very varied departments of science,—judging from my own feelings at the present moment, I cannot do better than express on their behalf the sincerest gratification at the high recognition you have bestowed on their scientific work.

For my own part, as the Davy Medallist, I may perhaps be permitted to speak at somewhat greater length. Thirteen years ago in this very room, at the Anniversary

Dinner of the Royal Society, I had the honour to return thanks to this Society for conferring on me the distinction of a Royal Medal. The President, Dr. Hooker, in handing to me the Medal, referred to the then novel instrument the Radiometer, and in the course of his remarks he made the following observation:—

"It is the mystery attending this phenomenon that gives it its great importance. There is evidently some action going on with which we are not at present acquainted; and there is no saying what a thorough investigation into the cause of the phenomenon may lead to."

From that date to the present I have not ceased to work at the elucidation of the mysteries accompanying high vacua. During this interval of thirteen years the theory of the Radiometer has been established on a firm basis. Since the advent of the Radiometer the Otheoscope has been devised and its action elucidated; lines of molecular pressure in high vacua have been illuminated so as to render visible to the bodily eye those actions which hitherto had been seen only by the eye of faith; molecular shadows have been projected; luminous streams have been deflected and magnetised; platinum has been melted by molecular impact; the existence of matter in a fourth state—"radiant matter"—has been demonstrated; and the strikingly brilliant phenomena of phosphorescence in high vacua have been discovered.

The results of these investigations I have embodied in ten memoirs and Bakerian Lectures which have appeared in the *Philosophical Transactions*, in eighteen papers which have been inserted in the *Proceedings of the Royal Society*, and in fifteen other papers published elsewhere.

In the spectroscopic examinations which these researches necessitated I constantly met with a bright citron-coloured line, sometimes strong, at others only a ghost of a line, but always in the same place, and presumably due to the same cause. The hunting out of this phantom line has been a work of many years. At last I found it to be due to yttria, while a corresponding red line was tracked to samaria.

Here a new field, indeed I may say a new world, of research unfolds itself to the chemist. The phosphorescent light from yttria gave in the spectroscope a complicated and beautiful series of coloured lines. But these lines varied in different specimens of the same earth from different localities, some being strong and others weak almost to extinction. Chemical tests showed that in each case the earth was free from known impurity, and for a long time the interpretation was inexplicable. I was confronted with a series of inscriptions from the molecular world, written in a strange and baffling tongue, and requiring a Rosetta stone to give the first step to decipherment. How the key of the mystery came into my hands, and what resulted therefrom, are now matters of history. The meaning of the lines, their positions and variations, is gradually becoming clearer and clearer, and to me this is what they seem to be saying:—

They tell me that in matter which responds to every test of an element, which possesses an atomic weight and combines with other matter in definite proportions, there still exist minute shades of difference among which a process of selection is possible.

They tell me that the time-honoured distinction between elements and compounds, as it exists in the Lavoisierian and Daltonian chemistry, must be modified to make room for a vast array of intermediate bodies, or as I have elsewhere called them Meta-Elements, capable of isolation and identification.

They tell me that there exist degrees of rank in the hierarchy of the chemical elements, some being, so to speak, more elemental than the others, some still waiting to be discovered, whilst others may have disappeared and are no longer existent under the conditions in which we are now placed.

They tell me, again, that our chemical elements are products of the action of forces on a state anterior to

matter, which I have designated as Protyl; that these elements owe their present stability in that they are the outcome of a struggle for existence, a Darwinian development by chemical evolution; that just as in the organic world we have the "survival of the fittest," so here we have the "survival of the most stable" or possibly of the "most inert."

There are other lessons as yet only indistinctly whispered, lessons which, possibly to-day, but certainly in days to come, will be seized on and interpreted.

But I will no longer weary you with speculations which have not yet received full and final confirmation. It only remains for me to thank you for the high distinction of the Davy Medal—a distinction all the more welcome as it has only once previously been awarded to one of our own countrymen. I deeply appreciate the kind reception you have given me and the very gratifying remarks with which the presentation has been accompanied.

Refreshed and stimulated by your friendly words of encouragement, I shall continue to apply myself to what Darwin called "the vivid pleasures of investigation." I shall attack with renewed energy the problems of Radiant Matter Spectroscopy, and do my utmost "to pluck out the heart of the mystery."

NOTICES OF BOOKS.

Force and Energy: A Theory of Dynamics. By GRANT ALLEN. London: Longmans, Green, and Co.

MOST of our readers will doubtless have become acquainted with Mr. Grant Allen as the author of not a few biological treatises, memoirs, and articles, which, if containing little that is novel in fact or profound in theory, have the great merit of presenting the truths of evolution in a form "understood of the people." But to meet with him as the author of a novel physical speculation is certainly an unexpected event.

Passing over a somewhat lengthy "apology," which stands in place of a preface or introduction, and in which the author avows himself no physicist, we come at once to the gist of the author's views. We find a novel definition of "energy" and "force," both being included under "power," as the widest generalisation of dynamics. With Mr. Allen, power is "that which produces or destroys, increases or lessens, motion in any particle or particles of any substance whatsoever cognisable by man."

Force the author defines as "a power which initiates or accelerates *aggregative* motion, whilst it resists or retards *separative** motion in two or more particles of ponderable matter, and possibly also of the ethereal medium."

Energy, on the contrary, is a power which resists or retards *aggregative* motion, while it initiates or accelerates *separative* motion in two or more particles of ponderable matter, or of the ethereal medium."

Of force, the author tells us, there are four species, exerted respectively between masses, molecules, atoms, and "electrical units." These are gravitation, cohesion, chemical affinity, and electrical affinity. Energy is, in like manner, classified as molar, molecular, chemical, and electrical. The term "chemical energy," it is expressly pointed out, is used to signify not a combining but a decomposing agency. The "Persistence of Force" and the "Conservation of Energy" are included under a head entitled the "Indestructibility of Power."

The essential point, then, in the author's dynamical consideration is the general opposition proclaimed between all the forces or aggregating agencies on the one hand and the energies or segregating agencies on the other. Of course Mr. Grant Allen or any other writer may claim the liberty of attaching novel connotations to any accepted

* The italics are our own.

term, and so long as no confusion is produced, the claim must be granted. But the question is:—Do the author's speculations throw any new light on physical and chemical phenomena, or do they point the way for future research? "Theories," said Dumas, "are like crutches; to find their value we must take them and try to walk with them." Now we do not see clearly that Mr. Grant Allen's *aperçu*—the term is his own—will enable us to reach any vantage ground which we do not occupy already, or which we are not in process of reaching.

It may also be asked whether the complete antagonism between forces and energies—using the terms in the author's manner—which we here find is justifiable? Heat is here classified as a species of energy, as a power which resists aggregation. Yet the author admits that heat is necessary to make carbon combine with oxygen, and that light is required to effect the union of hydrogen and chlorine. Surely, then, heat and light may be regarded, according to circumstances, either as "forces" or "energies."

The picture of the gradual degradation of the universe and of the waste of its energies by transfer to the ether, "the great waste-heap of the universe," is given in great detail in the second part of the work. But we encounter here nothing but what is familiar.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 21, November 19, 1888.

On the Collection of the Ancient Greek Alchemists.—M. Berthelot.—The publication both of the Greek text and of the translation is now completed, with the exception of the index and analytical tables. The fourth part contains works and extracts ascribed to various ancient authors, Pelagius, Ostanes, Johannes the Archpriest, Comarius, Justinianus, Jamblichus, and pseudo-Moses. The two last-mentioned writings seem to contain portions contemporary with the papyrus of Leyden. The sixth part contains the Byzantine commentators: Christianus, Philosophus anonymus, Cosmas Hierotheus, Nicephorus Blemmides. The fifth part is the most interesting. It contains technical treatises on working in gold, on tempering and colouring bronze and iron, on casting bronze, gilding iron, the manufacture of leaf gold, the colouration of artificial precious stones, the treatment of pearls, the preparation of a lye of wood-ashes, the manufacture of beer and soap. Most of these treatises seem to have been derived from a great Byzantine manual of applied chemistry, composed about the eighth or ninth century.

Benzidine Hydrochlorates: their Dissociation by Water.—P. Petit.—Benzidine forms a mono- and a dihydrochlorate. The former is stable in its solutions. The dihydrochlorate is decomposed by water according to two distinct laws. When the concentration does not reach 5.4 grms. per litre, a constant fraction, $\frac{1}{11}$, is decomposed into monohydrochlorate and free hydrochloric acid. If the concentration exceeds 5.4 grms. per litre, crystalline monohydrochlorate is deposited, and the quantity of the dihydrochlorate dissolved is the sum of two terms, the one constant, which is the fraction corresponding to 5.4 grms., the other proportional to the excess of the weight above 5.4 grms.

Bulletin de la Société Chimique de Paris.
Vol. I., Nos. 6 and 7.

Determination of Phosphoric Acid.—G. Linossier.—For separating and determining phosphoric acid on

author's principle, it may be precipitated as bismuth phosphate according to the indications of Chancel. To this end the solution of the phosphate, acidified with nitric acid, but free from hydrochloric and sulphuric acids, is raised in a porcelain capsule to a temperature close upon boiling, and mixed with an excess of bismuth nitrate. Bismuth phosphate is very rapidly deposited, and the supernatant liquid is quite clear. It is decanted upon a filter, and the precipitate is repeatedly washed with boiling water by decantation. When pouring the washings upon the filter it is important to let fall along with them only the smallest possible trace of the precipitate. Cease to wash when the liquid no longer shows an acid reaction. The filter is then placed over a clean flask, and there is poured upon it a saturated solution of sulphuretted hydrogen to decompose the traces of bismuth phosphate carried along with the washing water, and to set the phosphoric acid at liberty. The mass of the precipitate remaining in the capsule is treated in the same manner with sulphuretted hydrogen, and well agitated with a saturated solution of this gas. When the reaction seems complete the clear liquid is poured upon the filter and the residue treated with a fresh quantity of sulphuretted hydrogen. Finally, the bismuth sulphide is thrown upon the filter and washed with a solution of sulphuretted hydrogen, until a drop of the filtered liquid no longer reddens Poirrier's orange. The filtrate is freed from sulphuretted hydrogen by boiling, and the phosphoric acid is determined by titration with decinormal solution of soda, using orange 3 (Poirrier) as indicator. The exact point of neutralisation may be difficult to seize, as the change of colour is gradual in dilute solutions. It is, therefore, well to place, side by side of the flask containing the acid liquid, a similar flask, containing a volume of water equal to the volume of the phosphoric solution, coloured with the same quantity of orange, and to continue the addition of soda until the colour in both flasks is exactly alike.

Determination of Chlorine.—G. Linossier and M. Lignon.—The author precipitates the solution of chloride cold, or slightly heated with a slight excess of mercurous nitrate. Mercurous chloride very quickly collects at the bottom of the capsule. The clear liquid is decanted upon a small filter, the precipitate is repeatedly washed by decantation in the capsule, pouring each time the washings upon the filtrate as free as possible from any trace of the precipitate. The remaining treatment is exactly analogous to that directed by the author for the determination of phosphoric acid.

New Method of Preparing Acetones.—M. l'Abbé J. Hamonet.—The author gives detailed directions for the preparation of propione or diethyl-carbonyl, of butyrene or dipropyl-carbonyl, and of cœnanthylone or dihexyl-carbonyl.

MISCELLANEOUS.

Dinner to Dr. A. W. Williamson, F.R.S.—As our readers are aware, a subscription was set on foot soon after the retirement of Dr. Williamson from the Chair of Chemistry at University College, to secure some lasting memorial of his services to our science. Although the subscription was limited to a guinea, it has been so warmly responded to by his old students and colleagues, that it was possible to commission the Hon. John Collier to paint Dr. Williamson's portrait. On Wednesday next, December 12th, at 4.30 p.m., this portrait will be presented to University College by Sir Henry Roscoe on behalf of the subscribers. In the evening of the same day, at 7 p.m., Sir Henry Roscoe will take the chair at a dinner of the subscribers at the Freemasons' Tavern.

Royal Institution.—The following are the lecture arrangements before Easter:—Professor Dewar, six lectures (adapted to a Juvenile Auditory) on Clouds and Cloud-land; Professor G. J. Romanes, twelve lectures constitu-

ting the second part of a Course on Before and After Darwin (The Evidences of Organic Evolution and the Theory of Natural Selection); Professor J. W. Judd, four lectures on The Metamorphoses of Minerals; Dr. Sidney Martin, four lectures on the Poisonous Action of Albumenoid Bodies, including those formed in Digestion; Professor J. H. Middleton, four lectures on Houses and their Decoration from the Classical to the Mediæval Period; Professor Ernst Pauer, four lectures on The Characters of the Great Composers and the Characteristics of their Works (with Illustrations on the Pianoforte); and eight lectures by the Right Hon. Lord Rayleigh on Experimental Optics (Polarisation, the Wave Theory). The Friday Evening Meetings will begin on January 25th, when a Discourse will be given by Professor G. H. Darwin; succeeding Discourses will probably be given by Professor W. C. McIntosh, Sir William Thomson, Professor A. W. Rücker, Mr. Harold Crichton Browne, Professor Oliver Lodge, Professor Archibald Geikie, the Rev Alfred Ainger, the Right Hon. Lord Rayleigh, and other gentlemen.

MEETINGS FOR THE WEEK.

MONDAY, 10th.—Medical, 8.30.
Society of Arts, 8. (Cantor Lectures). "Light and Colour," by Capt. W. de W. Abney, F.R.S.
TUESDAY, 11th.—Institute of Civil Engineers, 8.
Royal Medical and Chirurgical, 8.30.
WEDNESDAY, 5th.—Society of Arts, 8. "Explosives," by W. H. Deering.
Microscopical, 8.
Pharmaceutical, 8.
THURSDAY, 13th.—Royal, 4.30.
Mathematical, 8.
Institute of Electrical Engineers, 8.
FRIDAY, 14th.—Astronomical, 8.
Quekett Club.

TO CORRESPONDENTS.

A. B. E.—An examination has to be passed before becoming a Fellow of the Chemical Institute. No examination is necessary to become a Fellow of the Chemical Society. Apply to the respective Secretaries.

A Balance with Weights, nearly new, cost £14; Platinum Crucible, cost £3; Muffle, cost £2 10. What offers?—Apply 14, Dudley Road, Tipton, Staffordshire.

TO CHEMICAL MANUFACTURERS AND OTHERS.

TO LET.—Extensive Premises, situate between Wrexham and Ruabon, on a branch of the Great Western Railway, consisting of—
Large Shed, 167 feet long × 25 feet wide.
Buildings, 37 feet × 28 feet, 67 feet × 27 feet, and 25 feet × 20 feet.
Wharf, 500 feet long, with Railway Siding running the whole length.

Within easy access, by rail, of several large Gas Works.
Apply to GEO. E. WOODFORD, RUABON.

TO MANUFACTURING CHEMISTS AND OTHERS.

THE METROPOLITAN BOARD OF WORKS will meet at the Office of the Board, Spring Gardens, S.W., on FRIDAY, the 14th day of December, 1888, at Twelve o'clock at noon precisely, and will then be prepared to open Tenders by Parties who may be willing to contract for the supply of such quantities of Sulphurous Acid as may be required by the Board in the ensuing year. The probable consumption will be about 1500 carboys (of 1 cwt. each), and the deliveries will have to be effected at such times and in such quantities as may be directed. Parties desirous to submit Tenders may obtain a copy of the Specification, Form of Tender, and information as to places of delivery, on application to the Chemist of the Board, at the Office, Spring Gardens, between the hours of nine a.m. and four p.m. (on Saturdays between the hours of nine a.m. and 2 p.m.) until Thursday, the 13th day of December, 1888. The Tenders, which must be on the form supplied from this Office, and addressed to the Clerk of the Board, are to be delivered at the Office by ten o'clock on Friday morning, 14th December, and no Tender will be received after that hour. The parties tendering must be in attendance at the Board at Twelve o'clock on the last mentioned day, and any Tender which is not fully filled up in every particular will be rejected. The Board do not bind themselves to accept the lowest or any Tender.

J. E. WAKEFIELD,
Clerk of the Board.

Spring Gardens, S.W.,
December 5th, 1888.

WEGELIN AND HÜBNER, Halle-on-Saale, MACHINE WORKS AND IRON FOUNDRY.

Representatives: NICKELS & Co., 150, Holborn, London, E.C.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37,746,
with increased effect through abolishing the noxious spaces; best
Air-Pump for Compression and Evacuation; useful effect up to 90
per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment,
with Attachment for Filtration with Exclusion of Air; in Wood,
Iron, or Bronze every desired size

Experimental Filter Presses

in Wood, Iron or Bronze.

Filtration Experiments, if desired, carefully conducted in
our Laboratory).

Steam Pumps & Transmission Pumps,
horizontal, vertical, mounted on column, Wall Pumps, Pumps for
Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids.
"Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or
Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids,
any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof,
i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c.
Also Small Ice Machines for Families, Laboratories,
Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure,
or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Com-
pound Steam Engines.
From 2—150 horse-power]

Steam Water Pumps,

newest, most approved Construction, taking up little room, and
especially suitable for placing in Wells, with great efficiency; up
to large sizes.

Compressors driven by Steam or Belt,
for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon
Ether, Alcohol, Acetone, Water; In Iron or Copper. (Extraction
Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.
Montejus for Sulphuric Acid, Mixing Vessels, Still, Pans,
and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin
Refineries, Resin Distilleries, Paraffin Works, Tar Dis-
tilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest
References for our above-named Specialities on
Application.

F. & M. LAUTENSCHLÄGER,
24, ZIEGEL STR.,
BERLIN N.

MANUFACTURERS AND CONSTRUCTORS OF CHEMICAL
BACTERIOLOGICAL, TECHNICAL, AND MICROSCOPICAL
APPARATUS.

Large stock of Beakers, Gas-Burners of newest design, Evaporat-
ing Basins, Stands for Burettes, Water-baths, Balances of best
finish, Apparatus for Testing Human Food, &c., &c.

Gas Regulators for different temperatures ready filled for use.
Glass Jars for anatomical preparations, all sizes, and Bacteriological
Apparatus with latest improvements as speciality.

We shall be glad to give estimates for new complete laboratories.

WHOLESALE—EXPORT.

REPORT OF RESEARCHES ON SILICON COMPOUNDS AND THEIR DERIVATIVES.*

PART I.

By J. EMERSON REYNOLDS, M.D., F.R.S.,
Professor of Chemistry, University of Dublin.

THE present investigation was undertaken some years ago with a view to examine the action of the silicon haloids—but more especially of silicon tetrabromide—on various compounds containing nitrogen, as our knowledge of the relations of silicon and nitrogen is extremely limited.

It was ascertained at an early stage of the inquiry that the bromide of silicon is much superior to the chloride as a reagent with nitrogenised compounds, but since the bromide had apparently not been obtained in any quantity even by its discoverer, Serullas, considerable time had to be devoted to working out a method for the production of a sufficiently large supply of this material. The method adopted is described in the full paper.

In the purification of the crude tetrabromide a new *chlorobromide†* of silicon was discovered, which boils at 141° C. This proved to be the compound SiClBr_3 , which was required to complete the series of possible chlorobromides of silicon.

The first group of nitrogen compounds subjected to the action of silicon tetrabromide included the primary thiocarbamide or sulphur urea, obtained by the author in 1863, and the allyl-, phenyl-, and diphenyl-thiocarbamides.

All these are shown to unite with silicon tetrabromide, and afford the highly condensed compounds—

These are more or less vitreous solids, with the exception of the allylic compound, which is a transparent and singularly viscous liquid. All are dissolved and decomposed by water and by alcohol.

The action of alcohol on the compound $(\text{H}_4\text{N}_2\text{CS})_8\text{SiBr}_4$, was studied in detail, and it is shown that not only do ethyl bromide, thiocyanate, and diethylic silicate result, but that the representatives of two new classes of thiocarbamide derivatives are formed.

The first of these is a beautiful *tetrathiocarbamide* compound, whose formula proved to be—

which may obviously be written

This body separates from alcohol in fine masses of crystals resembling sea anemones in appearance, which melt at 173–174°, and begin to decompose at 178–180°. The synthesis of this substance was effected by heating ammonium bromide with thiocarbamide.

Several homologues of the above *tetrathiocarbamid-ammonium bromide* were produced by synthetic methods; some of these contain chlorine or iodine instead of bromine.

The following are examples of the compounds formed in the course of this part of the investigation :—

By the action of silver nitrate on the tetrathiocarbamid-ammonium bromide the crystalline *dithiocarbamide* compound with silver bromide was obtained—

This was subsequently produced by the direct union of thiocarbamide with the pure silver haloid. The compound—

was also obtained in fine crystals, as were other similar substances.

A *trithiocarbamide* compound is also formed during the action of ethyl alcohol on $(\text{H}_4\text{N}_2\text{CS})_8\text{SiBr}_4$, but it is much more soluble than that which first separates. It is also crystalline, and its analysis and reactions lead to the formula—

Hitherto only mono- and di-thiocarbamide derivatives have been known; but the results above stated in outline prove that tri- and tetra-thiocarbamide compounds are formed in presence of silicon tetrabromide and certain other agents, which latter form addition products with the condensed amide.

So far, cases were only dealt with in which silicon tetrabromide combined with nitrogenised groups without loss of its halogen. The next stage of the inquiry involved the investigation of certain interactions in which the tetrabromide loses *all* its halogen. One of the chief results obtained in that direction forms the subject of a separate communication.

ON THE PREPARATION OF BORON.

By S. G. RAWSON, B.Sc.

THE ordinary methods for the preparation of this element present a certain amount of difficulty when only a small quantity of it is required. Usually boric anhydride is fused with metallic sodium and the resulting mass exhausted with water. The decomposition is one which takes place with great violence, besides involving the use of special apparatus, such as an iron crucible, and the subsequent washing consumes much time. For these reasons, therefore, the following method seems to offer some advantages.

A mixture of 3.5 grms. B_2O_3 and 11.0 grms. CaF_2 is taken and treated in a flask with concentrated sulphuric acid. A continuous stream of boron fluoride can be readily obtained by gently warming the flask. The gas is then passed through a piece of hard glass tubing on which three or four bulbs have been blown and in each of which a little potassium has been placed. The bulbs are heated in turn, decomposition occurring with the formation of potassic fluoride and liberation of boron. The mass is then thrown on to a filter and can be readily and completely washed, leaving the boron behind. The experiment is also an interesting one to show on the lecture table from the easy and rapid manner in which the boron is set free.

Silicon fluoride treated in a similar manner also readily decomposes, depositing silicon as a brown amorphous powder, from which the fluoride of potassium can be removed by washing, first with cold and subsequently with hot water. Considerable quantities of boron and silicon can be thus obtained in a very short time.

University College, Liverpool.

* Read before the Royal Society, November 22, 1888.

† The chlorine required for the production of this compound was derived from the crude bromine (which always contains chloride of bromine) used in preparing the tetrabromide.

THE CALORIMETRIC BOMB AS A COMBUSTION FURNACE FOR ULTIMATE ANALYSIS.

(PRELIMINARY NOTE)

By ARNOLD EILOART, B.Sc.

THIS bomb, with its use in calorimetry, has been fully described by M. Berthelot ("La Force des Matières Explosives," 3rd Ed., i., 227); *Ann. Ch. et Phys.*, 6th Series, vi., 546). Briefly, it consists of a strong lidded crucible made of platinum cased in steel. A stopcocked tube passes through the middle of the lid, and near one side of it an insulated platinum wire, and the lid screws air-tight on to the crucible.

With this bomb M. Berthelot and his followers (see references above and *Ann. Ch. et Phys.*, 6th Series, x., 433) have proved several facts important for the purposes of this paper.

(1) Substances representative of some of the most important classes of substances containing carbon, as charcoal, methane, cellulose, glucose, saccharose, naphthalene, anthracene, phenol, benzoic acid, quinone, fumaric acid, may be burnt in the bomb with the utmost completeness and certainty. This is done by filling the bomb with oxygen at 24 atmospheres pressure, and igniting the substance therein by an electric current. Compounds containing nitrogen, *e.g.*, hydrocyanic acid, aniline (*Comp. Rend.*, cv., 1087), azoxybenzol, azobenzol, hydrazobenzol, and phenylhydrazine (*Comp. Rend.*, cvi., 1668) have been burned. Only in the case of aniline is it mentioned that any nitrous oxides were formed, and then their quantity was "very small."

(2) The bomb was capable of closure so perfect that not a bubble of gas escaped through the water in which the instrument was immersed during the operations.

These facts point the way to a method of ultimate analysis which would be an advance on any previous method, still greater than is effected by the bomb in calorimetry. The chief ground of doubting the utility of the bomb in analysis is that M. Berthelot himself nowhere mentions such an application of it; although he shows that the amount of carbonaceous gas burnt in the bomb may be estimated by weighing the CO₂ formed. For this he draws the gas, by means of a mercury pump, through a potash tube with guards and re-fills the exhausted bomb with air, the exhaustion through the potash tube and the re-filling being repeated three times. But this is by no means recommended as an analytical method. Moreover, the oxygen was saturated with water, so that no determination of water produced by combustion was made. Also, the original volume of air was left in the bomb, so that from the nitrogen some nitric acid was formed (30—4 m.grms.).

But drive out this air with dry oxygen, and why should not the water and CO₂ be estimated by simply introducing small weighed absorption vessels into the bomb before the experiment and noting the increase of weight after allowing time for complete absorption of the products of combustion and after displacing the oxygen with air? One of the chief objections would of course be expense. The original bomb of M. Berthelot contained 662 grms. of platinum, and its internal capacity was nearly 250 c.c. But since then a bomb described as "much smaller" has been found to answer. Moreover, the weight required for analysis is less than half that used for a calorimetric experiment, so that the size of the bomb may be reduced still further.

Many other difficulties will readily suggest themselves, though none I think insuperable. It is not my purpose to discuss them here, and it is not necessary to say much as to the importance of overcoming them, and making not only the discomforts of the combustion room, but the necessity for the room itself, a thing of the past. In the hope of hastening this result I publish this note, although I am

very sensible that the value of such suggestions should be proved, and as a rule proved beforehand, by special experiment. For this I have unfortunately not yet had opportunity, but in the meantime it is well that investigators who are conducting experiments with the bomb should be asked to keep in mind the analytical as well as the calorimetric bearing of their work.

EXPERIMENTS UPON ALUM BAKING - POWDERS, AND THE EFFECTS UPON DIGESTION OF THE RESIDUES LEFT THEREFROM IN BREAD.

By Prof. J. W. MALLET, University of Virginia.

(Concluded from p. 278).

12. Laboratory Experiments on the Effect of Treating a Liquid having the General Composition of Gastric Juice with Aluminum Hydroxide and Phosphate.

SOME light seems to be thrown on the nature of the interference with digestion of these aluminum compounds by a few experiments made with an artificial gastric juice, prepared by dissolving 2.5 parts of (real) hydrochloric acid and 3 parts of a pretty easily soluble "pepsin" in water enough to produce 1000 parts of the liquid.

A weighed quantity (about 50 grains) of either aluminum hydroxide or aluminum phosphate, carefully prepared and dried at 212° F., as described above (10), was added to a quantity of this liquid containing somewhat more hydrochloric acid than would suffice for complete solution, and the mixture allowed to stand, with occasional shaking, in a stoppered glass flask at about the temperature of the human body (98° or 99° F.) for a period which might be taken to represent something like the term of gastric digestion (2 or 2½ hours). The liquid was then filtered and a definite fraction of it evaporated to dryness at a low temperature over a water-bath, and the residue dried at 212° F. and weighed. This residue was afterwards heated to redness in the air until all water was expelled and all organic matter burned off, and a second weighing made. In like manner the undissolved matter left upon the filter was dried at 212°, weighed, heated to redness in the air, and again weighed. A definite portion of the original liquid (artificial gastric juice) which had not been treated with either of the aluminum compounds was also, for the purpose of comparison, evaporated to dryness, the residue dried at 212°, weighed, burned, and weighed again. And, finally, weighed portions of the particular lots of aluminum hydroxide and aluminum phosphate employed were treated in the same way, and the loss of weight at 212°, and after heating to redness, ascertained.

From the data thus obtained it appeared that in each case a part of the aluminum was dissolved by the feebly acid liquid, while on the other hand a part of the organic matter used as pepsin was rendered insoluble and left with the undissolved portion of the aluminum compound present. When aluminum hydroxide was used from 47.3 to 61.8 per cent of it was dissolved, from 5.6 to 14.5 per cent of the pepsin being at the same time precipitated or thrown down from the solution. When aluminum phosphate was used the proportion of it taken up by the liquid ranged from 38.2 to 49.1 per cent and from 25.8 to 32.9 per cent of the pepsin was rendered insoluble. These figures represent but approximate quantitative results for the organic matter precipitated, as it was found extremely difficult to secure equal drying of the materials weighed, and moreover in the case of the aluminum hydroxide, added to the artificial gastric juice, a turbid gelatinous liquid was produced which it was impossible to filter to a state of perfect clearness. It was shown, however, distinctly that there was a double effect on the liquid treated, both the principal constituents of natural gastric juice being influenced; the hydrochloric acid was in part

charged with the aluminum used, taken up in soluble form; and there was simultaneous removal from solution of the organic matter represented by the digestive ferment pepsin. This double effect may fairly be taken to indicate impairment of digestive efficacy of the natural gastric juice if exposed to similar treatment.

13. *Probable Similar Relation of the Aluminum Compounds Experimented on to the Soluble Organic Matter of Food as to that of the Gastric Juice.*

Although I have not as yet made any direct experiments on this point, it seems highly probable that the second of the two effects above noticed, namely, the partial precipitation in insoluble form of some of the organic matter of a liquid having the general composition of gastric juice, would be brought about also if soluble albumenoid and other forms of organic matter of food were similarly treated. The aluminum hydroxide or phosphate apparently entering into a sort of more or less loosely united compound with such organic matter, somewhat as is the case when, in dyeing, colouring substances of organic origin are fixed by aluminum mordants. If so, there would be apparent a further explanation of the impairment of digestion of the aluminum compounds in question, a part of the food, already in soluble form, being rendered insoluble on the one hand, while on the other the integrity of at least one of the most important digestive fluids of the body being interfered with, the power of dealing with the portion of the food requiring solution would be reduced.

14. *General Summary of the Conclusions Reached.*

The main points which seem to be established by the experiments under discussion are, briefly stated, the following:—

(a). The greater part of the alum baking-powders in the American market are made with alum, the acid phosphate of calcium, bicarbonate of sodium, and starch.

(b). These powders, as found in retail trade, give off very different proportions of carbonic acid gas, and therefore require to be used in different proportion with the same quantity of flour, some of the inferior powders in largely increased amount to produce the requisite porosity in bread.

(c). In these powders there is generally present an excess of the alkaline ingredient, but this excess varies in amount, and there is sometimes found on the contrary an excess of acid material.

(d). On moistening with water, these powders, even when containing an excess of alkaline material, yield small quantities of aluminum and calcium in a soluble condition.

(e). As a consequence of the common employment of calcium acid phosphate along with alum in the manufacture of baking-powders, these after use in bread-making leave at any rate most of their aluminum in the form of phosphate. When alum alone is used the phosphate is replaced by hydroxide.

(f). The temperature to which the interior of bread is exposed in baking does not exceed 212° F.

(g). At the temperature of 212° F. neither the "water of combination" of aluminum hydroxide nor the whole of the associated water of either this or the phosphate is removed in baking bread containing these substances as residues from baking-powder.

(h). In doses not very greatly exceeding such quantities as may be derived from bread as commonly used aluminum hydroxide and phosphate produce, or produced in experiments upon myself, an inhibitory effect upon gastric digestion.

(i). This effect is probably a consequence of the fact that a part of the aluminum unites with the acid of the gastric juice and is taken up into solution, while at the same time the remainder of the aluminum hydroxide or phosphate throws down in insoluble form the organic substance constituting the peptic ferment.

(k). Partial precipitation in insoluble form of some of the organic matter of food may probably also be brought about by the presence of the aluminum compounds in question.

(l). From the general nature of the results obtained the conclusion may fairly be deduced that, not only alum itself, but the residues which its use in baking-powder leaves in bread, cannot be viewed as harmless, but must be ranked as objectionable, and should be avoided when the object aimed at is the production of wholesome bread.

A NEW METHOD OF CHEMICAL ANALYSIS IN WHICH CAPILLARY ATTRACTION PLAYS AN IMPORTANT PART.

By CHARLES W. PHILLIPS, Cincinnati, Ohio.

INVENTED in 1872, but not made known on account of the many difficulties arising in connection therewith.

The first difficulty was to obtain pure chemicals. I do not say that I have them even now, so that in my work there are probably some errors that will have to be corrected at some future time, but the many beautiful, characteristic, and delicate reactions have induced me to make the matter public at this time with the hope that some one with better facilities at command may supply what I have omitted and verify what I have done.

The second difficulty was to obtain pure paper. For many years I hunted for a paper that would give even ordinary satisfaction, but could not find it. Recently I received a sample of incomparable filtering paper, which I found admirably adapted to the purpose, and have used it in these experiments.

These difficulties having now been largely overcome, I shall proceed to describe the reactions of all the important metals of the 6 groups with 4 reagents, making in all 116 reactions, leaving many curious and beautiful reactions with special reagents for some future paper. Believing this scheme of vast importance, I expect to develop it as rapidly as possible and hope to be able to adapt it to quantitative work. One of the principal advantages of this method is that experiments can be filed away for future reference, and in medico-legal investigations the actual evidence can be carried into court and filed away with other legal documents. I have on hand some experiments made sixteen years ago, in which the majority of the reactions are as distinctly visible as the day they were made.

If you wish to verify the following reactions, first prepare your test-papers as follows:—

Chemically pure white filtering paper, having a close grain, is dipped in a 10 per cent solution of ferrocyanide of potassium, laid on a pane of glass and dried in the open air or preferably in a drying oven at 150° F. Then prepare a 10 per cent solution of neutral chromate of potassium, also one of bromide of potassium, and one of hyposulphite of sodium, and proceed with each as before.

Having prepared your test-papers, rule them off in small squares, or otherwise with a lead pencil, and mark each block or space with the symbol of the metal you intend to apply to it. Place your papers on a clean pane of glass, and after once you commence to apply your tests the papers *must not be moved* until perfectly dry. Take a piece of glass tubing seven inches long and $\frac{3}{8}$ inch inside diameter, draw it out to a point and file off the point, then hold it in the flame constantly rotating until it forms a perfectly round end with an aperture of about $\frac{1}{16}$ inch. A half-inch of liquid drawn up into this tube is amply sufficient for 25 different tests.

Dip your tube in the solution to be tested, say potass. sulph., draw up a little of the liquid, wipe off the outside of the tube with a towel, and place the tube vertically upon the square marked K on each one of your test-papers; then blow out any liquid remaining in the tube;

throw into the larger end of the tube a few drops of distilled water from a wash-bottle, and blow it out as before; this will serve to clean the tube, which must be done very carefully before dipping into another solution. Proceed in this way with all the metallic elements. The following are the reactions with ferrocyanide of potassium test-paper as I have observed them. I have no doubt many chemists will at once assert that the blue reactions recorded are due to iron as an impurity, but I have as yet been unable to find chemicals that would not give these reactions. These reactions may be due to the acid radical and not to the metal. The peculiar rings and halos are not characteristic of the ferrocyanide of iron.

K.—No reaction, white centre washing out to a yellowish ring.

Na.—No reaction, white centre washing out to a yellowish ring.

NH₄.—White centre washing out to a pale blue ring which finally turns green.

Ba.—White centre washing out to a light yellow ring.

Sr.—White centre washing out to a thin olive-grey ring.

Ca.—White centre washing out to a pale yellow ring.

Mg.—White centre washing out to a yellow and finally a citron-yellow ring.

Al.—A pale blue homogeneous centre, surrounded by a white ring, and washing out to a thin greenish ring.

Cr.—Pale blue centre, surrounded with a pale greenish ring, and a thin green ring and a green halo.

Zn.—A homogeneous white spot.

Mn.—A very light brown centre, surrounded by a white ring, and that surrounded by a light yellowish-brown ring.

Ni.—A grey centre, surrounded by a white ring and then by a thin light yellow-brown ring.

Co.—A dark purple centre with rosy purple fringe, surrounded by a thin blue ring, followed by a thicker white ring, followed by another thin blue ring.

Fe''.—A sky-blue centre, surrounded by a paler blue fringe, surrounded by a white ring and then a grey ring.

Fe'''.—A dark blue centre, surrounded by a navy-blue ring, surrounded by a dark blue fringe.

Ag.—A reddish brown centre, with a lighter fringe surrounded by a white ring, surrounded by a citrine ring.

Hg'.—A Nile-green spot, changing sometimes to a green centre and sometimes to a white centre. When the centre is green it is surrounded by a white ring and then by a greenish yellow ring; when the centre is white it is surrounded by a broad pale bluish green and then a thin greenish yellow ring.

Pb.—A very light neutral grey centre, surrounded by a broad white ring and a narrow lemon-yellow ring.

Hg''.—A light pale blue centre, surrounded by a white ring, surrounded by a light heliotrope ring, surrounded by a thin citrine coloured ring.

Bi.—A light blue, changing to a sage-green centre with a whitish edge, surrounded by a bluish grey ring, surrounded by a thin Vandyke brown ring, resembling the margin of a crenate leaf, surrounded by a broad sage-green ring and a broad blue halo changing to yellow and vanishing.

Cu.—A reddish brown or terra-cotta spot, with serrulate margin.

Cd.—A pale blue homogeneous centre, surrounded by a white ring, surrounded by a thin citrine ring. The margin is entire. Is scarcely distinguishable from *Al*, only that the white ring is not so broad, and on close inspection the outside ring does not have so much greenish cast.

Au.—A mottled cream and ashes-of-roses centre, surrounded by a broad pea-green ring, surrounded by a broad old-gold coloured ring with a distinct undulate margin.

Pt.—A whitish green centre with deltoid chocolate-coloured spots in the margin, surrounded by a lemon-yellow ring, surrounded by a thread-like old-gold coloured ring.

Sn''.—A pale blue centre, surrounded by a broad white ring, surrounded by a distinct thread-like crenate green border, surrounded by a bluish halo.

Sn'''.—A large heliotrope centre, surrounded by a light blue halo.

Sb.—A dark blue centre, irregular margin, surrounded by a light blue ring, surrounded by a distinct thread-like greenish ring, surrounded by a very large light blue halo, its diameter being three or four times the diameter of the dark blue centre.

As'''.—At first a delicate flesh colour, changing to white, surrounded by a thin yellow ring.

As''''.—At first a delicate salmon, changing rapidly to white, surrounded by a thin yellow ring.

Reactions with Neutral Chromate of Potassium.

K.—A white centre, surrounded by a broad pale yellow ring and a raised thin yellow ring.

Na.—A white centre, surrounded by a scarcely perceptible yellow ring.

NH₄.—An indistinct white centre, surrounded by a broad pale yellow ring, surrounded by a broad orange-yellow ring.

Ba.—A pale yellow centre, surrounded by a distinct white ring, surrounded by a broad yellow ring.

Sr.—A white centre, surrounded by an indistinct yellow ring.

Ca.—A white centre, surrounded by distinct salmon-yellow ring.

Mg.—A white centre, surrounded by a lemon-yellow ring.

Al.—A peculiar very light lavender-grey coloured centre, surrounded by an orange-yellow ring, then by a yellow ring and a raised thin sulphur-yellow ring.

Cr.—A brownish lavender centre, surrounded with a pure lavender ring, surrounded by a thin serrated garnet ring with a thin orange-yellow margin.

Zn.—Yellow centre, surrounded with a white ring, surrounded with an orange-yellow ring, then with a lemon-yellow ring, and with a raised thin greenish yellow ring.

Mn.—A single dark-coloured spot, the size of a pin point, surrounded by a speckled surface composed of white, yellow, and amethystine flakes, surrounded by an irregular serrated or stellated amethyst border, surrounded by a broad brownish yellow ring and a narrow lemon-yellow ring, surrounded by a thin greyish yellow ring. This reaction is very characteristic.

Ni.—A leather-coloured centre, surrounded by a clouded white ring and a broad brownish red ring.

Co.—A homogeneous centre of a colour resembling scorched paper, surrounded by a thread-like ring of deep garnet, surrounded by an orange-yellow ring.

Fe''.—A plum-coloured spot with a metallic lustre. No rings.

Fe'''.—A rich gold or orange-yellow centre, surrounded by a pale yellow ring and a thin orange-red or brick-coloured ring, with a slight orange halo.

Ag.—A circular magenta centre of surpassing beauty, with a scalloped border of lighter tint, surrounded by a white ring, and a yellow ring, and a thread-like raised yellow ring. This reaction is very characteristic.

Hg'.—A fiery brick-red circular centre, surrounded by an irregular ring of lighter tint, surrounded by a white ring, an orange ring, and a raised lemon-yellow ring. Almost as characteristic as the preceding.

Pb.—A yellow centre, surrounded with a yellowish white ring, a tawny-coloured ring, and a slightly raised thread-like lemon-yellow ring, surrounded by an indistinct tawny-coloured halo.

Hg''.—A light salmon centre, surrounded by a very light salmon ring, a tawny-coloured ring, and a thin raised lemon-yellow ring.

Bi.—A heliotrope centre, surrounded by a yellow ring, and terra cotta margin with an orange halo, changing, on drying, to an almost white centre, surrounded by a very

narrow yellow ring, and a dark brown thread-like ring, and an orange halo.

Cu.—Deep maroon, changing to a light bismarck, which on drying becomes whiter, surrounded by a light terracotta ring, surrounded by a thread-like ring of bismarck brown, and a very narrow orange border.

Cd.—A tawny-coloured centre, surrounded by a ring of lighter tint and a broad orange ring, and then a yellow ring.

Au.—A mottled centre, composed of light yellow and dark lavender-grey spots, surrounded by a ring of darker shade, resembling slate colour, and a lemon-yellow ring and a raised thread-like yellow ring.

Pt.—A tawny coloured centre, surrounded by a lighter ring, surrounded by an orange ring and a lemon-yellow ring with a raised thread-like border.

Sn''.—A bluish white centre shading off through light yellow into light brown, surrounded by a dark brown thread-like ring, forming a ragged or dentate margin with an orange halo.

Sn'''.—A white shading off into a more distinctly bluish colour, surrounded by a dark citron coloured ring with irregular edge and an orange halo.

Sb.—A white shading off into a greenish white centre, surrounded by a thread-like scalloped cinnamon-brown ring, surrounded by a greenish halo shading off into brown, orange, and yellow, the diameter being twice the diameter of the centre.

As'''.—A light green centre, surrounded with a darker green ring, surrounded by a broad yellow-green ring.

As''''.—A light green, changing to yellow, surrounded by white, surrounded by a thin light yellow-green ring, surrounded by a yellow ring with raised edge.

Reactions with Bromide of Potassium.

K, Na, NH₄, Ba, Sr, Ca, Mg, Al, Cr, Zn, Mn, Ni, and Pb produce no perceptible reaction.

It is a peculiarity of this reagent that all the rings have entire margins, none have rough or jagged edges.

Co.—A very light rose-coloured centre with a thin light margin and a brownish white halo.

Fe''.—A very light yellow-grey centre, surrounded by a broad cream-coloured ring and a thread-like ring of yellow grey. No halo. Sometimes the cream-coloured ring changes to orange. In this instance, only once in five experiments.

Fe'''.—A bright yellow-brown spot, by transmitted light blood-red. No rings; no halo.

Ag.—A yellow-white centre, which turns a dark grey on exposure to light, surrounded by a broad white ring with raised edge.

Hg'.—A very white centre, surrounded by a broad ring the colour of the paper, surrounded by a thin raised white ring. Centre does not darken by exposures to light.

Pb.—Hardly ruffles the paper; can scarcely be seen.

Hg''.—A large centre the colour of the paper, surrounded by a thin white ring.

Bi.—A beautiful greenish-white centre, surrounded by very thin yellow and orange rings, and a delicate, light salmon halo, whose diameter is twice that of the greenish-white centre.

Cu.—A pale blue-green centre, surrounded by a broad light brown ring. Very characteristic.

Cd.—A white centre, surrounded by a very faint brownish-white ring, surrounded by a distinct white ring.

Au.—An orange centre somewhat resembling the ferric reaction but lighter in tint, and appearing orange by transmitted light, having a faint yellow edge, surrounded by a ring the colour of the paper, and that by a white ring. The ring just inside the white ring changes to light blue.

Pt.—A lemon-yellow centre. Surrounded by a faint brownish ring, which by transmitted light looks quite distinct, surrounded by a light yellow ring.

Sn''.—A white spot, hardly perceptible, but having a faint yellow halo when viewed by transmitted light.

Sn'''.—A white spot with a very light fawn-coloured halo.

Sb.—A white centre, surrounded by a thread-like orange ring, surrounded by a faint yellow halo, whose diameter is three times the diameter of the centre. Best seen by transmitted light.

As'''.—White, by transmitted light a series of light drab concentric rings.

As''''.—White, by transmitted light a light drab, somewhat lighter than above.

Reactions with Hyposulphite Soda.

K, Na, NH₄, Ba, Sr, Ca, Mg, Al, Cr, Zn, Mu, no reaction.

Ni.—White centre, surrounded by a Vandyke brown stellate ring, no halo. Quite characteristic.

Co.—Large white centre, surrounded by a thin dark green ring, changing to bronze-green, surrounded by a sky blue ring. Very characteristic.

Fe''.—A very light brown or light salmon centre, surrounded by a broad light brown ring.

Fe'''.—A sulphur yellow centre, surrounded by a light brown and then a darker brown irregular ring.

Ag.—A yellow centre rapidly changing to brown and then to dark brown, surrounded by a light brown irregular ring. Characteristic.

Hg'.—A black centre, surrounded by an irregular grey ring. Characteristic.

Pb.—No reaction, except a very pale yellow colour by transmitted light.

Hg''.—At first produces a white spot, which changes to a variegated spot, having lemon-yellow and light brown irregular spots, surrounded by a white ring and an irregular slate-coloured ring.

Bi.—A light centre, with yellow-brown irregular ring. The whole changing to a dark reddish brown.

Cu.—A greenish yellow centre, surrounded by thin yellow and orange rings. The centre finally changes to a very light copper colour, surrounded by a broad greenish yellow ring, and that by a thin yellow and orange ring.

Cd.—A white centre, with a very faint brownish white ring, hardly perceptible, except by transmitted light.

Au.—A peculiar light brownish grey splattered spot mingled with light yellow, almost indescribable, but very characteristic; no rings.

Pt.—A light brown or brownish grey mottled centre, surrounded by a white ring, surrounded by a light brown ring.

Sn''.—A white centre, surrounded by a broad faint yellow or greenish yellow ring.

Sn'''.—Same as above, only with a thread-like white ring on the outer edge.

Sb.—A white centre, surrounded by a thin yellow and orange-yellow ring.

As'''.—No perceptible reaction.

As''''.—No perceptible reaction. — *Pharmaceutical Record*, Nov. 1, 1888.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, December 6th, 1888.

Mr. WILLIAM CROOKES, F.R.S., President, in the Chair.

Messrs. Lewis Edmunds, J. B. Readman, and J. Cowper were formally admitted Fellows of the Society.

Certificates were read for the first time in favour of Messrs. Charles Lightfoot Barnes, The Steps, Bromsgrove, Worcester; Albert Cooper, Grimstone Lawn, Haven Green, Ealing; William Hepworth Dixon, Heatherdale, Woodford Green, Essex; B. S. Gott, B.A., Wesley

College, Sheffield; Frederick Charles Garrett, B.Sc., 4, Kempson Road, Walham Green, S.W.; Robert J. Gow, Halebank Terrace, Ditton, Widnes; Edward Gudeman, Ph.B., P.O. Box 3001, New York City; Allan Twistleton Hall, Inglebank, Newlands, Hull; John A. Hall, 126, Lloyd Street, Greenhays, Manchester; Cecil Leigh, care of A. H. Allen, 67, Surrey Street, Sheffield; Arthur Lloyd MacLeroy, M.A., 12, George Street, Bathwick Hill, Bath; Frank K. Peace, Monton Grange, Eccles, near Manchester; Charles W. Priestley, B.Sc., Abbey House School, Tewkesbury; John Provis, Poldice House, North Adelaide, South Australia; Edgar Richards, Office of Internal Revenue, Washington, D.C.; Siegfried Ruhemann, Ph.D., M.A., University, Cambridge; Walter Venis, Benares, India.

The following were elected Fellows of the Society:—Messrs. Charles M. Adams, John Hope Belcher, B.A., William Berry, William Dunsmore Bohm, Frank Bower, James Edward Brunker, George Alexander Byrn, John Morrow Campbell, Vaughan Cornish, B.Sc., William Douglas, Arthur George Everard, Henry Forth, Frederick Bickell Guthrie, John Hansfield, Urban Arthur Jackson, Alfred Battye Knapps, Oscar Lowman, B.A., Ph.D., William Marshall, George Edward Perry, Hubert N. B. Richardson, John S. Rigby, John Sanderson, Thomas Oliver Sandolt, William Jay Schieffelin, Arthur Landauer Stern, William Taylor, Charles Turner, John Laurence Van-Geyzel, I. T. Ainslie Walker, Edward Dalrymple Walrond, B.A., Frederick W. Warrick, Edward J. Way, Ernest W. Whieldon, R. W. Woosnam.

The following papers were read:—

86. "A Method of Determining Vapour-density, Applicable at all Temperatures and Pressures." By WILLIAM BOTT, Ph.D., Berkeley Fellow of Owens College.

The apparatus consists of a large Victor Meyer's bulb, carrying a detachable head-piece, which can be connected with the air-pump. The neck of the bulb communicates with a mercury pressure-gauge, which again is connected with a wide measuring tube attached to an adjustable mercury reservoir. The experiment is conducted as follows. The substance having been placed in the head-piece of the vessel, the latter is heated until the volume has become constant. The apparatus is then exhausted as far as may be requisite, and the reservoir so adjusted that the graduated measuring tube is filled with mercury. The pressure indicated by the gauge having been carefully noted, the substance is allowed to drop into the hot part of the vessel, and the surplus pressure produced by its evaporation is removed by drawing off an equivalent volume of air into the measuring tube until the initial pressure in the gauge has been restored. From the volume of gas measured in the graduated tube, the density referred to hydrogen is obtained by the formula—

$$d = 8484893 \frac{S(1 + 0.00367t)}{VP}$$

S=weight of substance; V=volume of gas in measuring tube; P=pressure of gas in measuring tube; t=temperature of gas.

DISCUSSION.

Prof. RAMSAY, remarking on a statement made by the author that he proposed to make use of the apparatus in studying the influence of pressure on dissociation, said that recent investigations had shown that the Victor Meyer form of apparatus was by no means a suitable one for the study of such problems; and he expressed the opinion that for this reason results such as those recently published by Nilson and Pettersson could not be accepted as final.

87. "Some Derivatives and New Colouring-matters of *a*-Pyrocresol." By WILLIAM BOTT, Ph.D., and J. BRUCE MILLER.

Trichlor-*a*-pyrocresol, $C_{15}H_{11}Cl_3O$, produced by direct chlorination of pyrocresol, forms fine, silky needles,

soluble in boiling benzene and chloroform, insoluble in all alcohol and ether; it melts at about 225°.

Dinitro-*a*-pyrocresol oxide, $C_{15}H_{10}(NO_2)_2O_2$, is obtained from *a*-pyrocresol oxide by careful nitration in the cold and subsequent treatment with alcohol. It forms yellowish white crystals, sparingly soluble in acetic acid and freely in hot nitrobenzene; it melts at 235°.

Tetramido-*a*-pyrocresol oxide, $C_{15}H_8(NH_2)_4O_2$, is obtained by reduction in acid solutions from the corresponding tetranitro-derivative; it is a greenish yellow powder, soluble in acids, and melts above 300°.

Diamido-*a*-pyrocresol oxide, $C_{15}H_{10}(NH_2)_2O_2$, prepared from dinitro-*a*-pyrocresol oxide, resembles the tetranitro-derivative in its properties.

Both amido-compounds can be diazotised, and the diazo-salts interact with phenols in alkaline solution. Two oxyazo-compounds have thus been obtained from β -naphthol, representing the first colouring-matters prepared from pyrocresol. Both interact with concentrated sulphuric acid in a characteristic manner, resembling safranin in their behaviour. The colouring-matters in the pure state are dark red powders, insoluble in water; they can be converted into soluble sulphonic acids by treatment with fuming sulphuric acid: the solutions dye silk and wool a fine maroon and salmon colour respectively.

By the action of ammonium sulphide upon tetranitro-*a*-pyrocresol oxide in alcoholic solution, a red and a yellow substance have been obtained, which are evidently azo-derivatives, but have not yet been examined more closely. The yellow substance is somewhat soluble in hot water, the solutions dyeing silk a fine yellow shade.

88. "Berberine." By W. H. PERKIN, Jun.

Several analyses of the base and also of its chlorhydride showed that these substances were not adapted to the purpose on account of their containing water of crystallisation, which can only partially be removed by dehydration: a fact which has been previously noticed by other chemists. Berberine appears to crystallise with 5 to 5½ mol. props. of water, 2 of which remain when the substance is dried at 100° till constant. Berberine chlorhydride, dried over sulphuric acid in a vacuum at a temperature of about 40°, has the formula $C_{20}H_{17}NO_4 \cdot HCl + 2H_2O$. The chloroplatinate, iodhydride, and nitrate, however, are well adapted for analytical examination, and the results which they afford agree closely with those required on the assumption that berberine is $C_{20}H_{17}NO_4$.

When oxidised with an excess of potassium permanganate in slightly alkaline solution, berberine yields, as principal product, hemipinic acid, $C_{10}H_{10}O_6$, as Schmidt and Schilbach (*Arch. Pharm.*, [3], 164—170) have already shown. In view of the interesting results lately obtained by Goldschmidt in his examination of hemipinic and methemipinic acids, the author has carefully re-examined the hemipinic acid from berberine, and is convinced that it is identical with that obtained by the oxidation of narcotine. The acid from berberine contains two (OCH₃) groups; on fusion with potash it yields protocathechuic acid, and on distilling it with ethylamine, hemipinethyrimide, melting at 96°, is formed. This latter substance possesses all the properties of the hemipinethyrimide obtained by Liebermann by the action of ethyl iodide on the potassium salt of hemipinimide (from narcotine), and thus the identity of the two hemipinic acids from berberine and narcotine is proved.

Besides hemipinic acid, small quantities of at least two other acids are formed by the oxidation of berberine; one of these melts at 238—242°, and appears to be identical with berberonic acid (or carbocinchomeronic acid?).

If berberine is carefully oxidised with a limited quantity of permanganate, a number of new substances are formed, three of which have already been obtained in a state of purity: a new acid, $C_{20}H_{17}NO_6$, which melts at 143°, and two neutral substances, $C_{20}H_{17}NO_8$ and $C_{20}H_{16}NO_7$, all of which yield protocathechuic acid (berberinic acid?) on

fusion with potash. The compound $C_{20}H_{17}NO_8$ melts at 236° ; it is insoluble in cold solutions of alkaline carbonates, but dissolves in potash, ammonia, &c., forming well-defined salts. The silver salt appears to have the formula $C_{20}H_{15}NO_8Ag_2 + 4H_2O$.

The compound $C_{20}H_{15}NO_7$ (?) melts at 150° and is insoluble in alkalis.

When heated with a fuming aqueous solution of hydrogen iodide, berberine yields methyl iodide and a phenolic substance which, from the analysis of its sulphate, appears to have the formula $C_{18}H_{13}NO_4$, being derived from berberine by the displacement of two methyl-groups. Several determinations of the number of (OCH_3) groups by Zeisel's method have shown that there are two such groups present in the berberine molecule.

The author has also examined berberinic acid—one of the acids obtained by Hlasiwetz and Gilm (*Fahresbericht*, 1864, 407), by fusing berberine with potash. This acid is decomposed on distillation into carbon dioxide and homopyrocatechol—a decomposition which proves that the acid must be looked upon as a carboxylic acid of this phenol.

The behaviour of berberine towards methyl and ethyl iodides, benzylchloride, &c., has also been studied; it appears in opposition to the results of Henry (*Annalen*, cxv., 133), that the alkaloid does not form additive compounds with these substances.

89. "The Action of Ammonia on Some Tungsten Compounds." By Dr. S. RIDEAL, D.Sc.

Wöhler, in 1858, found that a compound containing nitrogen, hydrogen, and oxygen was obtained by the action of ammonia on heated tungstic oxide, and also a compound containing nitrogen and hydrogen from ammonia and tungsten chloride; analyses of different specimens, however, gave varying results.

According to the author's experiments, ammonia effects the removal of a part only of the oxygen in tungstic oxide, and the black products vary greatly in composition, the average of many analyses agreeing best with the formula $W_5N_6H_3O_5$. When tungstic oxide is heated with ammonium chloride a similar black product is obtained. The amount of tungsten in different specimens varies between 83.9 and 81.0 per cent, the amount of nitrogen being less than in the compounds formed by means of ammonia; the mean composition of the products in this case may be represented by the formula WN_2WO_3 .

Ammonia acts on the yellow tungsten oxydichloride in the cold, forming ammonium chloride and a dark brown product which contains no nitrogen, and appears to consist of the dioxide WO_2 ; this interaction is similar to that of ammonia and chromyl dichloride.

Ammonia also acts on the red tungsten oxytetrachloride, forming a black compound; this contained 88.9 per cent of tungsten, but the amount of material was insufficient for a determination of the nitrogen. It seems probable that the product is the same as that found when ammonia acts on the hexachloride; i.e., the nitride W_2N_3 .

The action of ammonia on tungsten hexachloride was studied by Wöhler, who was of opinion that two compounds were formed, viz., $2WN_2 + W(NH_2)_2$ and $2WN + W(NH_2)_2$. This conclusion was based on determinations of tungsten and nitrogen in the samples prepared, but hydrogen was not estimated. The author has re-examined the black powder formed in the interaction in question, and has obtained numbers agreeing with those of Wöhler for the tungsten and nitrogen percentages, but he considers that the final product is free from hydrogen, and that it is the nitride W_2N_3 .

Dry ammonia has no action on finely divided tungsten, even at a red heat, and seems also to be without action on the blue oxide.

DISCUSSION.

The PRESIDENT drew attention to the anomaly involved in the use of the name *Tungsten* and the symbol W.

90. "Condensations of α -Diketones with Ethylic Acetoacetate." By FRANCIS R. JAPP, F.R.S., and FELIX KLINGEMANN, Ph.D.

In a paper entitled "Condensations of Glyoxal with Ethylic Malonate and Ethylic Acetoacetate," by Max Polonowsky (*Annalen*, ccxvi., 1), it is stated, as a reason for undertaking the investigation, that only the condensations of these ethereal salts with monaldehydes and monoketones have hitherto been studied. Polonowsky has evidently overlooked the fact that the condensation of a diketone—phenanthraquinone—with ethylic acetoacetate has been described by Japp and Streatfeild (*Trans.*, 1883, 27). The authors, therefore, wish to point out that they are engaged in investigating the condensation-product, $C_{20}H_{16}O_4$ —ethylic phenanthroxylene-acetoacetate—obtained by Japp and Streatfeild. The following interactions have been studied:—

By heating with formic acid (sp. gr. 1.22) at 130° the condensation compound is transformed into an isomeric crystallising in short needles melting at 177° . (Melting-point of the original condensation-product, 185° .) A study of the new compound leads the authors to represent the isomeric change thus:—

The iso-compound would thus contain a closed chain of 5 carbon atoms. It yields a hydrazone,—

melting with decomposition at $210-212^\circ$; whereas phenylhydrazine and the condensation product do not interact under ordinary conditions. The iso-compound is converted by acetic anhydride into an acetyl-derivative, $C_{20}H_{15}(C_2H_3O)_4$, which crystallises from benzene in thick needles melting at $165-170^\circ$. The iso-compound is converted by hydrolysis with aqueous caustic soda into the corresponding monobasic acid, $C_{18}H_{12}O_4$; this crystallises from alcohol in satiny needles, which melt at $267-269^\circ$ with decomposition. The condensation compound cannot be hydrolysed under these conditions (*vide infra*). With bromine the iso-compound gives a monobromo-derivative, $C_{20}H_{15}BrO_4$, which melts at 217° with decomposition, instead of the expected additive dibromide.

By heating with glacial acetic acid at $130-140^\circ$, the condensation-product yields a mixture of three compounds: (1.) A compound of the formula $C_{20}H_{14}O_3$, which crystallises in white silky needles, insoluble in boiling acetic acid, and which decomposes without previous fusion at about 285° ; this is formed with elimination of 1 mol. of water. (2.) The acetyl-derivative, $C_{20}H_{15}(C_2H_3O)_4$ (m.p. $165-170^\circ$), already mentioned as obtained from the iso-compound. This acetyl-derivative gives with phenylhydrazine the same hydrazone, and with caustic soda the same monobasic acid as the iso-compound, the acetyl-group being in both cases eliminated. (3.) A compound of the formula $C_{40}H_{28}(C_2H_3O)_2O_7$, which crystallises from acetic acid in rectangular plates melting at 227° ; this is formed only in small quantity—apparently by elimination of 1 mol. of water from 2 mols. of the acetyl-derivative.

Propionic acid converts the condensation-product into the before-mentioned compound, $C_{20}H_{14}O_3$, together with a propionyl-derivative, $C_{20}H_{15}(C_3H_5O)_4$, melting at 134° .

By boiling the condensation-product with sulphuric acid diluted with twice its weight of water, it is converted quantitatively into the iso-compound $C_{20}H_{16}O_4$, already described as obtained from formic acid (*vide supra*).

By boiling the condensation-product with alcohol to which a few drops of sulphuric acid have been added, it is converted into the compound $C_{20}H_{15}(C_2H_5)_4O_4$, which crystallises from alcohol in rectangular or prismatic crystals melting at $143-144^\circ$. But if the condensation-product is heated with a mixture of equal weights of alcohol and sulphuric acid at 100° , it gives a compound, $C_{17}H_{12}O_2$, which crystallises from phenol in microscopic six-sided plates, melting with decomposition at $276-277^\circ$; $C_{20}H_{16}O_4 + H_2O = C_{17}H_{12}O_2 + C_2H_5OH + CO_2$.

By warming it with an *alcoholic solution of hydrogen chloride*, the condensation-product is converted into the compound $C_{20}H_{15}ClO_3$, which crystallises from a mixture of benzene and light petroleum in lustrous flat needles melting at 140° .

The condensation-product is hydrolysed by *alcoholic potash* in the cold; heating must be avoided. The resulting acid is unstable, and has not been obtained in a crystallised condition; when freshly precipitated it dissolves in alkaline carbonate, but loses this property on standing. It dissolves in cold alcohol; on heating, the solution deposits a compound, $C_{17}H_{12}O_2$, which crystallises from phenol in star-shaped groups of needles, melting with decomposition at 259° ; this is isomeric with the compound already described as obtained by heating the condensation-product with a mixture of equal weights of sulphuric acid and alcohol.

The authors have also obtained a condensation compound from benzil and ethylic acetoacetate. It appears to belong to a different class from the phenanthraquinone compound. They also intend to study the condensation of ethylic benzoylacetate with benzil and phenanthraquinone.

91. "*Thionyl Thiocyanate.*" By G. C. McMURTRY.

Thionyl thiocyanate, $SO(SCN)_2$, is prepared by the action of thionyl chloride, dissolved in cold carbon bisulphide, on mercuric thiocyanate. It is an orange-coloured amorphous powder, insoluble in cold water, alcohol, ether, petroleum, phenol, chloroform, amyl alcohol, and acetic acid, but readily soluble in carbon bisulphide, and to a less extent in hot benzene.

92. "*Mercuric Chlorothiocyante.*" By G. C. McMURTRY.

Mercuric chlorothiocyante, $ClHg \cdot SCN$, or—

may be obtained by crystallising mercuric thiocyanate with mercuric chloride. It crystallises in monosymmetric prisms, sparingly soluble in cold water, but readily soluble in hot water and in alcohol.

93. "*The Action of Chromium Oxychloride on Pinene.*" By G. G. HENDERSON, B.Sc., M.A., and R. W. SMITH.

The authors find that pinene and chromium oxychloride interact very readily, forming a solid compound of the formula $C_{10}H_{16} \cdot 2CrO_2Cl_2$. This is decomposed by water, yielding an oil which may be purified by distillation with steam, and which has a composition expressed by the formula $C_{20}H_{33}OCl$. It is possible that this oil may be a mixture of the two compounds $C_{10}H_{18}O$ and $C_{10}H_{17}Cl$, but the authors were unable to separate it into two portions by steam-distillation; it is not attacked by alcoholic potash, does not combine with bisulphites, is unaffected by acetic chloride, and does not interact with either hydroxylamine or phenylhydrazine. When distilled under diminished pressure it loses the elements of a molecule of water, yielding an oil of the composition corresponding to the formula $C_{20}H_{31}Cl$.

94. "*Tectoquinone.*" By R. ROMANIS, D.Sc., Rangoon College.

In a former communication (*Trans.*, 1887) the author described a substance found in teak resin (*Tectonia grandis*), and also in the products of the destructive distillation of the wood, having the composition $C_{18}H_{16}O_2$, and the properties of a quinone. It may be separated from the tar by caustic soda, which dissolves the tar, leaving a curdy mass containing the quinone, mixed with a hydrocarbon of the composition C_nH_n , melting at 194° , and other substances. The quinone is separated by dissolution in boiling alcohol of 50 per cent, in which the other substances are insoluble; it separates as the liquid cools in a felted mass of soft woolly crystals; from strong alcohol it is deposited in oblique rhombic prisms of amber colour, resembling sulphur. It melts at 171° , sublimes slowly at ordinary temperatures, sensibly at $100^\circ C.$, and rapidly near its melting-point. By careful heating between watch-glasses it can be sub-

limed without decomposition, condensing in yellow rhombic plates. It is a very stable substance, dissolving in sulphuric and nitric acids, and being precipitated unchanged on dilution; apparently it is not acted on by fused potash. On heating it with absolute alcohol and potash, a deep crimson solution is formed, which deposits bronze-coloured crystals on cooling; on exposure to moist air, or on mixing with water, the crimson solution turns green and yellow, and the quinone is re-precipitated. The quinone is reduced if heated with zinc and acetic or chlorhydric acid in a sealed tube at $150^\circ C.$ The product is a resin soluble in alcohol and ether, the dilute ethereal solution showing a splendid blue fluorescence. A similar resinous product is formed by the action of iodine, phosphorus, and water, but in this case the principal products are volatile. These resinous products contain from 4.7 to 5 per cent of oxygen, showing that 40 per cent of the quinone is unreduced, and in fact it gradually separates from the resin in rhombic crystals. Analysis shows the composition of the reduction product to be $C_{18}H_{22}$ (m. p. 72° ?).

If the quinone be heated with soda-line and zinc, it yields a hydrocarbon melting at 194° , which crystallises from alcohol in four-rayed stars composed of twinned rhombic plates.

Dibromotectoquinone is obtained by the action of bromine at 100 — 140° . It crystallises in orange-yellow, slender needles, which are generally arranged in spherical clusters, soluble in ether and alcohol. On fusion it melts at 165° ; with potash it gives a blue or purple melt: this dissolves in water, forming a purple solution, from which acids throw down a yellow flocculent precipitate, no doubt a dihydroxyquinone.

Dinitrotectoquinone is a yellow powder obtained by the action of nitrosulphuric acid on the quinone. It is converted by sodium amalgam, or zinc and caustic soda, into a crimson substance.

If the quinone be heated for two hours with nitrosulphuric acid, and the solution be then diluted, a purple precipitate is produced, which dissolves in alkalis, forming a purple solution.

Tectoquinone may possibly be retenequinone, which has not yet been discovered. Retene melts at $99^\circ C.$; the product of the reduction of tectoquinone softens at 70 — 72° , but it is evidently a mixture.

95. "*The Decomposition of Nitroethane by Alkalies.*" By WYNDHAM R. DUNSTAN and T. S. DYMOND.

The authors have been engaged during the present year in studying the action of alkalies and of certain reducing agents on nitroethane. They observed in October, 1887, that nitroethane is gradually decomposed at ordinary temperature by contact with potassium carbonate or its aqueous solution; at 80 — 90° the action is completed in a few hours. The chief products of the change are potassium nitrite and an oily liquid having the formula C_6H_9NO , which boils at about 170° , at a somewhat higher temperature decomposing with the formation of what appears to be a pyridine derivative. The compound is not attacked when heated for 48 hours in a closed tube with concentrated chlorhydric acid, neither is it appreciably affected by reducing agents. It is readily oxidised by permanganate. It does not seem to be either a nitroso- or isonitroso-derivative. This compound is apparently identical with that described by Götting (*Annalen*, cxxliii., 104), who obtained it in Geuther's laboratory by heating together propyl iodide, sodium nitroethane, and sodium ethoxide. Its ready formation, together with potassium nitrate, from nitroethane by contact with potassium carbonate, is likely to have an important bearing on the question as to the constitution of the paraffin nitro-compounds, and the authors therefore intend to continue the investigation. They are induced to publish the present preliminary notice by the appearance, in a recent number of the *Berichte* (November, 1888, p. 710), of an abstract of a paper by Sokolow in the *Russian Chemical Journal*. It is there shown that by heating nitroethane

to 100—130° in closed tubes with sodium hydroxide or carbonate, the compound C_6H_5NO , described by Götting, is produced, and that if an alkyl iodide is present it takes no part in the change. Neither sodium hydroxide nor sodium carbonate attacks nitroethane at ordinary temperatures.

PHYSICAL SOCIETY.

December 8, 1888.

Prof. REINOLD, F.R.S., President, in the chair.

DR. A. GAMGEE, F.R.S., and Mr. A. P. Trotter, B.A., were elected members.

The following communications were read:—

“*Note on a Modification of the Ordinary Method of Determining Electro-magnetic Capacity.*” By Mr. J. W. W. WAGHORNE, D.Sc.

In determining capacity absolutely from the throw of a galvanometer and a steady deflection through a known resistance produced by the same battery, error may arise from the imperfect elasticity of the fibre (when short), and the resistances required are often greater than can be conveniently obtained. The latter difficulty may be overcome by taking a known fraction of the potential difference used for charging the condenser, to produce the steady deflection, and the former error may be reduced by observing the first swing due to the permanent current, instead of the steady deflection produced by that current. By adopting this latter device, the logarithmic decrement need not be determined, and the time required to make a measurement is considerably reduced. The formula for capacity (F) becomes—

$$F = \frac{t d_1 b}{\pi G d_2 a},$$

while t = periodic time in seconds, G = resistance of galvanometer circuit, d_1 and d_2 the throws due to the condenser charge and the permanent current respectively, and a and b the resistances in the battery circuit from the ends of which the potential differences used to produce d_1 and d_2 are taken.

The above expression is not strictly accurate, because the damping effects on open and closed circuit are not identical; but in the cases observed by the author where the damping is not serious, the difference is negligible. A modified form of Pohl's rocking key was shown, whereby the two throws d_1 and d_2 could be rapidly observed, and readings could be taken in opposite directions to eliminate error due to torsion of the fibre.

DR. THOMPSON pointed out that error frequently arises from the capacity of the key being appreciable where small condensers are being used, but the author stated that the modification was not intended for such cases.

Prof. AYRTON remembered having used, in conjunction with Prof. Perry, the throw due to the permanent current instead of the steady deflection, when experimenting with condensers containing E.M.F's, and believed they abandoned it on account of the difference in decrement on closed and open circuits.

MR. SUMPNER regarded galvanometers with small differences in damping, on closed and open circuits, as unsuitable for ballistic purposes, and mentioned a case in which the latter was only half the former.

MR. BOYS considered the damping would be modified by having the condenser joined to the galvanometer terminals, and thought the decrement should be decidedly different from that on pure open circuit.

In thanking the author for his paper, the PRESIDENT said that any improved arrangements of well-known experiments or of lecture apparatus would always be gladly received, and reminded members that in bringing such before the Society they would be carrying out one of the chief objects for which it was founded.

“*On Some Facts Connected with the Systems of Scientific Units of Measurement.*” By Mr. T. H. BLAKESLEY, M.A.

The author considers that the C.G.S. and Practical (Quadrant, Volt, Second) systems of units do not satisfy the requirements of a perfect system, in which the chief ends to be kept in view are:—1st, *Correlation*; 2nd, *Simplicity*; 3rd, *Comprehensiveness*; 4th, *Naturalness*; and 5th, *Convenience*.

In a properly *Correlated System* all the quantities considered should be so connected by the equations representing the laws of nature, that no coefficients are required in expressing any unit in terms of others; for *Simplicity*, quantities essentially the same should be measured by the same unit; and to be *Comprehensive*, the system should embrace all the physical ideas which occur; to be *Natural*, its units should be closely or decimally connected with natural units; and for *Convenience*, they should agree with established (though arbitrary) units, either actually or decimally.

In the two systems referred to, correlation has been more completely realised than any of the others, but simplicity is by no means satisfactory, and the want of comprehensiveness was discussed by Prof. Rücker at the last meeting. The “second” is unnatural in not being a decimal subdivision of the solar day, and the gramme is derived from the centimetre by assuming the density of water to be unity, whilst the inconvenience arising from the relation between the horse-power and the Watt or the erg is universally acknowledged.

Two general formulæ are given for converting magnitudes expressed in Practical and C.G.S. electro-magnetic measure into C.G.S. electrostatic units. Let k and h be the dimensions as regards length and mass when the quantities are expressed in the E.M. system, and n and q the corresponding numbers when expressed in the E.S. system, then 1 Practical unit = $3^{n-k} 10^{10n-11q+k}$ Electrostatic C.G.S. units, and 1 C.G.S. electro-magnetic unit = $3^{n-k} 10^{10(n-k)+11(h-q)}$ Electrostatic C.G.S. units, the 3 arising from “ v ” being taken as 3×10^{10} c.m.s. per second.

Though the formulæ may be found useful, the author thinks it would be far better to adopt one system for all measurements, and suggests a “Coalition System,” in which “ v ” is taken as the unit velocity. If in this system the “second” be retained, then the unit of length will be 30 earth-quadrants, and if the quadrant be taken (as in the present practical system) as the unit of length, then the unit of time will be $\frac{1}{30}$ sec. The influence of such changes on present standards is then discussed, and the relation between the new unit of power and the horse-power (H.P.) found to be unsatisfactory.

To endeavour to bring the H.P. and the unit of power into decimal relation, the author expresses the physical quantities in terms of length, time, and power, from a table of which it is evident what units were affected by changing the unit of power, and tables of converting factors are given, when the latter were taken as 0.746 Watt or as 7.46 Watts.

The correlation of temperature θ with the units is considered to be best effected by defining it so that $J=1$ in the equation $m l^2 t^{-2} = J m c \theta$, when “the unit of temperature change would be that through which unit energy in the form of heat would raise a unit of matter possessing unit specific heat,” and by choosing air at constant pressure as the standard substance, $1^\circ C. = 10^7$ C.G.S. (air) units.

A summary is given towards the end of the paper in which the union of the two electrical systems by choosing $\frac{1}{30}$ sec. as the unit of time is recommended, the effect of which is to make the unit of capacity $\frac{1}{30}$ Farad, and that of resistance 30 ohms. Before concluding, the author deprecates the practice of giving specific names to particular units, for, by so doing, subsequent necessary changes are made much more difficult.

Prof. RÜCKER expressed his opinion that temperature

would be best correlated by expressing it as energy, instead of making its dimensions $l^2 t^{-2}$ as suggested in the paper.

Dr. S. P. THOMPSON thanked the author for his prefix "megisto," denoting "multiply by 10^{12} ." Referring to the choice of air as the standard for specific heat, he remarked that convenient coincidences were not always to be trusted, and that the specific heat of air depended on the pressure to which it was subjected.

Some Improved Polarising Apparatus for Microscopes were exhibited and described by Dr. S. P. THOMPSON. For polariser, he uses an Ahrens Prism, and for analyser a flat ended one of his own design. The Ahrens prism is formed from a rectangular block of spar, two faces of which are perpendicular to the optic axis; two cuts parallel to the axis are made from the middle of one side to the ends of the opposite, and the cut faces are polished and cemented by Canada Balsam. A short prism with wide angle is thus obtained which can be readily fitted to the sub-stage of the microscope. The analyser, which consists of two wedges of spar, is mounted in a tube which fits on the eye-piece, and by recognising that the upper end need not be larger than the pupil of the eye, the author has been able to considerably reduce the length of the prism, and still keep the bottom end large enough to collect all the rays passing through the eye-piece.

Several ingenious methods of cutting spar so as to produce prisms with minimum waste were described and illustrated by models, and a "Nicol" made by the inventor at the age of 79 was exhibited.

Mr. LANT CARPENTER asked the exhibitor why he condemned analysers placed directly behind the objective; for in his experience this arrangement gave the most satisfactory results.

In reply, Dr. THOMPSON said his experience was decidedly different from that of Mr. Lant Carpenter, and mentioned that Ziess had abandoned the common arrangement and now introduced his analysers between the two lenses of his Huyghenian eye-pieces.

NOTICES OF BOOKS.

Townson and Mercer's Catalogue of Chemical and Physical Apparatus and Chemicals. Fourth Edition. London: 89, Bishopsgate Street Within, E.C.

THE successive editions of this catalogue show considerable modifications in accordance with the increasing nicety and delicacy of modern research and the introduction of new instruments of precision. The edition before us includes appliances not merely for chemical and physical, but even for physiological research. Thus we note that apparatus for the cultivation and study of bacteria are figured and described at considerable length.

Appliances for the analysis of gases, whether for purely scientific or for technical purposes, form a very conspicuous and important feature. Of gas-burettes, absorption-apparatus, absorption- and explosion-pipettes, and complete sets for the examination of chimney, furnace, and chamber gases, the analyst now finds an ample selection from which he may choose the instruments best suited for his particular purpose.

Sets of apparatus to suit particular cases, or such as may be required by students at any part of their course, are strongly represented here. Thus, we find the set officially recommended for the analysis of beer, of wines, of tobacco; the sets prescribed for the Royal College of Chemistry, for the Cambridge and Oxford examinations, the set used by beginners in the laboratory of University College, the Frankland and the Wanklyn instruments for water-analysis, the Wanklyn set for medical officers of health, the apparatus for the study of physics and chemistry as recommended by the Science and Art Department, and other sets, too numerous to be mentioned.

The price list of chemicals is not so extensive as some which we have met with, and does not include certain rarities, both organic and inorganic, which the investigator may occasionally require. But the reagents now in use are all here to be met with, and in particular the new indicators used in alkalimetry and acidimetry. We regret to see magenta figuring under the name "fuschine."

The devices of Mr. Fletcher for the production of heat by the combustion of gas and petroleum figure in an appendix, as do the pure standard solutions of Messrs. Sutton.

Under the head "Telephone Apparatus" we note a curious fact. The United Telephone Company will neither themselves sell instruments to lecturers, students, &c., nor will they allow anyone else to do so, under the threat of an action for infringement. It is fortunate that novel scientific instruments, processes, &c., are not kept out of the hands of experimentalists in a similar manner.

Messrs. Townson and Mercer's Catalogue is something decidedly more than a mere price-list. It both tells the student what apparatus he will need for any proposed course in chemistry and physics, and gives the analyst and the investigator many useful hints concerning the instruments which they will require. We must therefore pronounce it a valuable book of reference, which deserves its place in the laboratory.

On Two New Indium Chlorides, and on the Vapour-densities of the Chlorides of Indium, Gallium, Iron, and Chromium. By L. F. NILSON and O. PETTERSSON. (A Reprint from the *Zeitschrift für Physikalische Chemie*, ii., 10.)

THE authors show that indium possesses three chlorides, which are well characterised and permanent in the gaseous state. The trichloride, InCl_3 , is not appreciably volatilised at 440° , and at temperatures between 606° and 850° it has a vapour-density agreeing with value 7.584, calculated for the formula InCl_3 . Above 850° it undergoes a continuous dissociation, being probably split up into lower chlorides and free chlorine.

The dichloride, InCl_2 , has, at 958° , a density rather higher than should follow from its formula, = 6.362. At higher temperatures the density becomes normal. The monochloride has at 1100° — 1150° a density 5.296, which approximates to the calculated density = 5.140. The complete series of the indium chlorides gives an interesting proof that an element of the third group can appear in definite compounds as monovalent, divalent, and trivalent.

The authors assign to the two gallium chlorides the formulæ GaCl_3 and GaCl_2 . The calculated density of the former = 6.081, its experimental density at 606° being 6.144, and at 1000° — 1100° , 5.185. The calculated density of the dichloride = 4.859, its experimental density at 1000° — 1100° being 4.823. For ferrous chloride, FeCl_2 , they find a density of 4.340 at 1300° — 1400° , whilst calculation gives 4.375.

To the chromium chlorides they assign the formulæ CrCl_3 and CrCl_2 . For the former the theoretical density is 5.478, the experimental results being 5.517 at 1191° . The theoretical density of the dichloride 4.256 falls below the experimental value, which, even at 1500° — 1600° is still 6.224. This discrepancy the authors ascribe to the fact that chromous chloride cannot be perfectly gasified, even at the highest attainable temperature.

The Electricians' Directory and Handbook for 1889.—The 1889 Edition of this well-known Directory and Handbook is in preparation. The publisher, Mr. G. Tucker, 1, Salisbury Court, Fleet Street, London, E.C., asks us to notify that the time for receiving New Names, Addresses, Corrections, and Advertisements will shortly expire. The price of the Directory, which will be ready early in January, will be 4 shillings, post free.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 22, November 26, 1888.

New Experiments on the Determination of Nitrogen in Vegetable Soils.—MM. Berthelot and André.—The authors have instituted some novel experiments in order to ascertain what is the degree of accuracy in determinations of nitrogen in vegetable earth by skilled analysts operating at different intervals of time, and under different conditions, as well as the degree of stability of the nitrogen fixed in these soils, and submitted to different influences. They took, as terms of comparison, three distinct soils, preserved at the ordinary temperature in a place absolutely free from nitrogen, which renders any increase of this element in the soil impossible. To prevent any decrease in consequence of fermentations, oxygen was likewise excluded. The experimentalists took a soil in its natural condition, submitted it to spontaneous desiccation, and by grindings and siftings rendered it perfectly homogeneous. Half a kilo. of this powdered soil was placed in a large flask of 4 to 5 litres, filled with carbonic acid. It was agitated, let settle, and fresh carbonic acid was repeatedly introduced, until all the air in the soil was expelled. A 400 c.c. bottle was then taken, filled with pure CO₂, and the earth thus treated was introduced without contact with air. The bottle was closed with a ground stopper, smeared with vaseline. All these operations were performed in an atmosphere of pure carbonic acid, constantly renewed. After the lapse of four and a half months the soil was analysed, and was found not to have appreciably varied from its original composition.

Bulletin de la Société Chimique de Paris.
Vol. I., Nos. 6 and 7.

Hydratation of Methyl-amyl-acetylene: A New Acetone, Ethyl-amyl-carbonyl.—A. Béhal.—The new compound has the formula C₈H₁₆O. It is insoluble in water, possesses a penetrating odour, and its density at 0° is 0.8502.

The Mineral Matter in Natural Petroleums.—J. A. Le Bel.—The black colouring-matter of bitumens and natural petroleums has received the name asphaltine. Some samples of this product contain iron, lime, and sulphur. Markownikow and Oglobine found, in the ash of the petroleum of Baku, calcium, iron, alumina, copper, and traces of silver. Some samples contain as much as 10 per cent of sulphur. The author finds, in the ash of asphaltine, 13 per cent of silica, 17 iron oxide with traces of manganese, the rest consisting chiefly of lime and calcium sulphate. The interesting feature is the presence of silica, which cannot have been dissolved in the petroleum, and which affords an argument in favour of Mendeleeff's theory of the organic origin of mineral oils.

No. 8.

Action of Hydriodic Acid upon Allyl Iodide (continued).—H. Malbot.—The author's conclusions are that when a current of hydriodic acid is passed into allyl iodide there is first formed propylene iodide, an explosive body. If the current of hydriodic acid is too rapid the propylene iodide may suddenly decompose, even if surrounded by a freezing-mixture. If such sudden decomposition is partly or entirely prevented the propylene iodide may be partially or totally transformed into isopropyl iodide by the prolonged action of the hydriodic acid. There is no difficulty in admitting that the isopropyl iodide results from the combination of hydriodic

acid with nascent propylene, derived from a limited decomposition of propylene iodide; but the gaseous propylene produced by a sudden splitting up escapes without combining, except in closed vessels. Propylene may be obtained in abundance by cautiously passing a current of hydriodic acid into allyl iodide, and occasionally applying a slight heat. The best precaution consists in diluting the explosive body with an inert liquid; for instance, isopropyl iodide.

Certain Crystalline Metallic Molybdates.—Antoine Coloriano.—The author describes the zinc, manganese, and cobalt molybdates, which he has obtained in the crystalline state. The corresponding salts of nickel, cadmium, and iron have been produced, but not yet analysed.

No. 9.

Researches on the Molecular Weights of the Aluminium Compounds.—M. Roux and E. Louise.—The results of the author's experiments, both the determinations of the vapour-densities and the depression of the freezing-points of the solutions, demonstrate that the organic compounds cannot in any case be determined by the simple formula AlX₃, but must have the double formula Al₂X₆.

The Volumetric Determination of Acids.—G. Linossier.—A question of priority. The author contends that his process described *Bulletin* (vol. I., pp. 46, 353, 354) is not identical with that of M. Engel (vol. xlv., p. 524).

An Alleged Reagent for the Copper Salts.—A. and P. Buisine.—M. Aliamet stated in a former number of the *Bulletin* that a saturated aqueous solution of neutral sodium sulphite, to which a little pyrogallie acid has been added, gives a rose-coloured solution in very dilute solutions of copper. The authors find that this reaction certainly takes place, but that it is not characteristic of copper, being producible with dilute aqueous solutions of most metallic salts, and even with distilled water.

A Process for the Determination and Separation of Zinc.—J. Riban.—Already noticed.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale. Series 5, Vol. iii., No. 28.

Report by M. Biver on the Application of the Filtering Apparatus of M. Ladureau to Gas and Petroleum Motors.—This memoir cannot be intelligibly reproduced without the six accompanying figures.

MEETINGS FOR THE WEEK.

MONDAY, 17th.—Medical, 8.30.
Society of Arts, 8. (Cantor Lectures). "Light and Colour," by Capt. W. de W. Abney, F.R.S.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1517.

ISOMERIC NAPHTHALENE DERIVATIVES.*

THE following is an outline of the work accomplished during the past year in the reporter's laboratory, chiefly with the invaluable co-operation of Mr. W. P. Wynne, B.Sc.

In discussing the laws of substitution for naphthalene, attention was directed in the first report to the *alpha-law* as the dominant law; and it was pointed out that whenever departures from this law occur, as a rule either the conditions are such as to favour secondary changes—as in the formation of β -sulphonic acids at high temperatures in presence of an excess of sulphuric acid—or a radicle such as OH or NH_2 is present which exercises a special influence. It was mentioned, however, in the same report, that when β -chloronaphthalene is sulphonated by means of SO_3HCl , two isomeric acids are formed, which there is reason to believe are represented by the formulæ:—

The conditions are such that the formation of the β -acid cannot be attributed to the occurrence of secondary changes, such as in all probability take place when sulphuric acid is the agent; the production of this derivative, therefore, cannot well be reconciled with the *alpha law*, but is suggestive of the existence in the naphthalene molecule of a "plane of symmetry" passing through the $\beta^*\beta^*$ -carbon atoms in which an influence is exercised. The observations on isomeric change, briefly described in the last report, prompted us, however, to determine whether the α -acid could not readily be converted into the β -acid by heating: the results entirely favour the view that the latter acid is in reality the product of isomeric change, and that its formation is in no way an exception to the *alpha-law*. When the sulphonation was effected in the cold, only three to four per cent of the product consisted of the β -acid; after heating the product at 100° for half an hour the amount rose to eleven per cent; heating at 150° for one hour increased the proportion of β -acid to twenty per cent; and no less than fifty-three per cent was present after heating at 150° for five hours.

These results have led us to study the behaviour of the chloronaphthalenesulphonic acids generally when heated, in order to determine whether, and in what way, they

undergo isomeric change. In preparing the necessary material for these experiments we have converted the four isomeric modifications of betanaphthylaminesulphonic acid by Sandmeyer's method into the corresponding chloronaphthalenesulphonic acids, and by distilling these with phosphorus pentachloride, have prepared the corresponding dichloronaphthalenes. The designation of the amido-acid, the melting-point of the sulphochloride of the chloro-acid, and the designation and melting-point of the dichloronaphthalene are as follows:—

Betanaphthylamine-sulphonic acid.	Sulphochloride.	Dichloronaphthalene.
	m.p.	m.p.
(α) (Badische)	129°	(θ') 63.5°
(β) (Brönnner)	109°	(ϵ) 135°
(γ) (Dahl)	70°	(η) 48°
(δ) (Bayer and Duisberg) ..	86°	(δ) 114°

Isomeric Dichloronaphthalenes.—No less than 12 isomeric dichloronaphthalenes have now been described. The conventional plane symbol of naphthalenes serves to exhibit only ten, but a geometrical symbol may be constructed in accordance with the method followed by Herrmann in the case of benzene (*Berichte*, 1888, 1949) which foreshadows no less than sixteen. The following is a list of the reputed dichloronaphthalenes:—

(1)	m.p. = 34°
(2) α	m.p. = 38°
(3) η	m.p. = 48°
(4) θ	m.p. = 61.5°
(5) θ'	m.p. = 65°
(6) β	m.p. = 68°
(7) ζ	m.p. = 83°
(8) κ	m.p. = 94°
(9) γ	m.p. = 107°
(10) δ	m.p. = 114°
(11) ι	m.p. = 120°
(12) ϵ	m.p. = 135°

α - α -Dichloronaphthalenes.—Nos. 6, 7, and 9 in the list belong to this category and represent the three possible α - α -derivatives: β -dichloronaphthalene is undoubtedly the α^1 : α^4 homonuclear modification, being obtainable from naphthalene tetrachloride and from naphthionic acid; γ - and ζ -dichloronaphthalenes are heteronuclear compounds, and if no other evidence were forthcoming, the fact that the γ -compound has the higher melting-point would alone justify us in regarding it as the symmetrical α^1 : α^4 -derivative; since, however, it is obtainable from the nitrosulphonic acid isomeric with the α - α -acid known as the Schölkopf acid, which—taking Bamberger's researches into account—is a so-called *peri* or hetero-ortho-derivative, there cannot be any doubt that γ is 1: 4' and that ζ is 1: 1' dichloronaphthalene.

β - β -Dichloronaphthalenes.—Of the three possible β - β -modifications, δ - and ϵ -dichloronaphthalene are the two possible hetero-compounds; and from the high melting-point of the latter there can be practically no doubt that it is the symmetrical 2: 3' modification, the δ -compound being therefore the 2: 2' derivative.

α - β -Dichloronaphthalenes.—Four are possible, two hetero and two homonuclear. η - and θ' - (m.p. 63.5°) dichloronaphthalenes may be prepared, as above stated, from Dahl's and the Badische modification of betanaphthylaminesulphonic acid respectively, and also from two α -nitro-acids obtained by Cleve by nitrating naphthalene-betasulphonic acid; they are therefore undoubtedly α - β -compounds, and are probably both heteronuclear. If these arguments be correct, the one is 1: 2', the other 1: 3' dichloronaphthalene.

θ -Dichloronaphthalene (m.p. 61.5°) is either the 1: 2 or the 1: 3 modification. *α -Dichloronaphthalene*, the product of the action of alkali on naphthalene tetrachloride, is undoubtedly a homonuclear compound. The modification melting at 34° , prepared by Cleve from chlorobetanaphthol and chlorobetanaphthylamine, is also homonuclear;

* Third Report of the Committee, consisting of Professors Tilden and Armstrong (Secretary), appointed for the purpose of investigating Isomeric Naphthalene Derivatives. (Drawn up by Professor Armstrong). Read at the British Association, Bath Meeting, 1888.

this latter is an *alphachloronaphthalene* derivative (Cleve), so that the dichloronaphthalene melting at 34° , if not the 1 : 2 is the 1 : 3 variety. By exclusion, it would follow that *alpha*-dichloronaphthalene is the third β - β -, i.e., β^2 - β^2 -dichloronaphthalene.

κ - and ι -dichloronaphthalenes have thus far been omitted from consideration; the former is probably non-existent, the method by which it is said to have been prepared being one which is very unlikely to afford a dichloronaphthalene. It is not improbable that the ι -compound will also be found non-existent; if on treating naphthalene with chlorine a small quantity of an isomeric heteronuclear tetrachloride be formed, and this lose its α -chlorine atoms, ϵ -dichloronaphthalene would result, and it is possible that this substance in an impure state may have been regarded by mistake as a distinct substance.

Isomeric Dichloronaphthalenesulphonic Acids.—With the object of further characterising and determining the individuality of the dichloronaphthalenes, the study of their sulphonic acids, to which reference was made in the last report, has now been extended to all. The chief result of interest is the fact that the dichloronaphthalene melting at 34° yields certainly two, perhaps three, isomeric sulphonic acids; the sulphochloride of the one acid crystallises in minute prisms melting at 168° , that of the other in massive prisms melting at 105° .

The dichloro-acids prepared by Widman by chlorinating naphthalene- α - and β -sulphochlorides have also been examined. That from the β -sulphochloride yields when hydrolysed β -, that from the α -sulphochloride what appears to be β -dichloronaphthalene, m.p. 61.5° .

Addendum.—Since the meeting of the Association, Erdmann and Kirchhoff (*Annalen*, 247, 366) have described the results of experiments on the synthetic production of

chloronaphthalene derivatives which they contend afford proof of the constitution of the γ , η , and θ varieties of dichloronaphthalene. Their method consists in preparing chlorophenylparaconic acids by interaction of succinic acid and chlorobenzaldehydes; by distilling the acids chloronaphthols are obtained, from which corresponding dichloronaphthalenes are prepared by distillation with phosphorus pentachloride. The conversion of phenylparaconic acid itself into α -naphthol is supposed by Fittig and Erdmann to take place in the manner indicated by the accompanying symbols. (See preceding column).

Assuming that the chloro-acids undergo a similar change, the acids derived from ortho- and parachlorobenzaldehyde should each yield but a single chloronaphthol, and that from the metachlor-aldehyde should alone be capable of yielding two isomers, viz. :—

Actually they obtained eventually from the metachloro-acid η -dichloronaphthalene (m.p. 48°); and as ϵ -dichloronaphthalene (m.p. 83°) is undoubtedly the 1 : 1' derivative they regard the η as the 1 : 3' derivative. The orthochloro-acid was found to yield γ -dichloronaphthalene, and hence they regard this as the 1 : 4' derivative—a conclusion which harmonises with previous views. θ -dichloronaphthalene (m.p. 61.5°) was prepared from the parachloro-acid, and accordingly this is represented to be the 1 : 2' derivative.

But these conclusions are entirely based on the assumption that the naphthol-hydroxyl is derived from one of the carboxyl groups of the succinic acid, as indicated by the symbols given above; there is, however, no reason why it should not be derived from the COH group of the aldehyde, and in this case the η would be the 1 : 2' and the θ the 1 : 3' derivative. In any case this objection entirely deprives Erdmann and Kirchhoff's arguments of their force: as in the case of benzene, there is little doubt that the constitution of naphthalene derivatives will be determined eventually by the study of naphthalene derivatives and not by synthetic methods of the character of those in question.

ON THE RAPID AND SURE DETECTION OF ANTIMONY IN MINERALS.

By ALEXANDER JOHNSTONE, F.G.S.,

Assistant to the Professor of Geology and Mineralogy in
Edinburgh University.

MINERALS which contain antimony, when heated *alone* before the blowpipe on charcoal, or with the *addition* of three or four parts of fusion mixture ($K_2CO_3 + Na_2CO_3$), yield dense white fumes of antimonious oxide,* which in great measure escape into the atmosphere, but which also in part become deposited on the charcoal support, forming a well-marked white sublimate, coat, or incrustation of the oxide.

Those results, though certainly in most cases very useful indications, do not furnish to the satisfaction of the mineralogist sound, conclusive evidence of the presence of antimony in the mineral tested, seeing that several other

* Not altogether antimonious oxide (Sb_2O_3) according to Dittmar. That chemical authority asserts that a small portion of the coat is composed of the amorphous antimony tetroxide (Sb_2O_4).

bodies occurring in the mineral world give, when heated before the blowpipe, exactly the same or nearly similar reactions. As a consequence of the hitherto inconclusive blowpipe evidence, mineralogists have usually considered it essential when engaged in correct work to supplement those indications by means of the accurate but tedious method of the ordinary wet way qualitative chemical analysis.

With a view to remove the necessity of consuming so much valuable time over the certain identification of antimony the author wishes to bring under the notice of mineralogists the following exceedingly simple but thoroughly trustworthy test, which he discovered and successfully applied whilst working amongst the various metallic ores of antimony.

To the white coat which will invariably form on the charcoal if the mineral containing antimony be properly treated and heated before the blowpipe add, by means of a narrow glass tube, a single drop of ammonium sulphide. If the white sublimate is composed of antimonious oxide, then the portion touched by the drop (or the part touched by the edge of the drop) will immediately become converted into the well known and highly characteristic reddish or orange sulphide of antimony.

As no other white coat producible on charcoal by heating a mineral in the blowpipe flame becomes reddish or distinctly orange in colour when treated as above with ammonium sulphide, the value of this easily applied test must at once be apparent.

LIEBREICH'S DEAD SPACE IN CHEMICAL REACTIONS.

By GEORGE WATSON, F.C.S.

IN the December part of the *Journal of the Chemical Society* occurs an abstract account of Liebreich's experiments on the dead space in chemical reactions, or the space exempt from any chemical change taking place in a liquid, and as no explanation of the phenomena is there given, I venture to suggest what appears to me a probable one, to wit, that the phenomena in question are solely caused by the surface energy of the glass vessels in which the liquids are contained.

From Liebreich's experiments the following conclusions are drawn:—1st. No chemical change is initiated in the layer of liquid immediately below the meniscus. 2nd. The rate of chemical change varies as the diameter of the vessel in which the liquid is contained, being slower the smaller the diameter, and *vice versa*. 3rd. In capillary tubes no chemical change whatever is engendered.

These results may all be caused by the surface energy of the glass. For, take any glass dish, say, for the sake of clearness, a test-tube, and consider how its internal surface energy will influence a liquid placed in it. The glass exerts an attractive force on the liquid immediately contiguous to it, tending, as it were, to densify the liquid. A stress is thus set up, radiating to the internal circumference of the test-tube from a vertical line cutting the axis of the cylinder of liquid. This produces a downward vertical stress, giving rise to a concave meniscus, and increasing the surface-tension of the liquid. The distribution of force or of strain in the layer of liquid just below the meniscus must be different, therefore, from that deeper down, and any chemical change taking place in the liquid may thus be influenced. If the effect be a retarding one in the case of a concave meniscus, then, if the liquid were placed in a tube whose walls gave a repellent effect instead of an attractive one (forming a convex meniscus), we should expect the influence to be now an accelerating one. The dead space should be transformed into one of greater vitality than the rest of the liquid.

In the same way may be explained the fact that no

chemical change was found to take place when the liquids were contained in capillary glass tubes. For, imagine the liquid to be contained in a square glass dish having one side capable of being moved inwards to any required closeness to the opposite side, and that a suitable chemical change is about to begin in the liquid. Then, by sliding in the movable side, one of the diameters of the dish is being continually decreased, and the starting of the chemical change will be simultaneously continually postponed, until, when the two sides have come so close together that a capillary plane has resulted, the postponement has become infinitely long, *i.e.*, the chemical change never begins. Similar considerations also show why variations in the diameter of the test-tubes give corresponding variations in the rates of the change.

It might be surmised, therefore, that if a vessel were filled completely and in such a way that no meniscus was formed, then no differentiation in the rate of the change should result, and this is confirmed by Liebreich's own experiments; the case in which a full test-tube closed by a piece of parchment gave a dead space being probably due to osmotic stress set up by the parchment in its vicinity.

And this explanation does not seem so improbable when we consider the many cases in which the local increase of surface energy produced by scratching the sides of the containing vessel hastens the formation of precipitates in those cases in which a precipitating stress exists. A good illustration of this is seen in the following experiment:—If some antimonious chloride be dissolved in a saturated solution of sodic chloride, a liquid is obtained which is quite clear at first, but which, being in a state of instability, deposits, on standing, a portion of its antimony as basic salt. If scratches be made on the glass, however, in the newly prepared liquid, such scratches are in a very short time—indeed almost at once—coated by a deposit of basic salt, the liquid otherwise remaining clear. This result is due to the slight increase of surface energy produced locally by the scratching, and inasmuch as a certain quantity of muscular energy is expended in producing an abrasion, causing the disappearance of its equivalent of cohesive force, and the appearance of the same amount of surface energy, it is evident that the surface energy of all solids is dependent on their intrinsic cohesive force; for any mass of solid may be viewed as having been originally part of a larger mass, and as having been formed from it by breaking or sub-division. Increase of surface is the inevitable concomitant of comminution, and comminution is the disappearance of so much cohesive force.

THE ACTION OF AMMONIA ON METALLIC MAGNESIUM.

By H. N. WARREN, Research Analyst.

MAGNESIUM, heated in a current of dry ammonia, provided the temperature be kept below redness, apparently undergoes no change, but, on examining the same at the termination of the reaction, a marked distinction is observable as regards its chemical properties, refusing to melt below a red heat, and burning, when ignited, with most violent decrepitations. If, while in this form, it be still further heated, the temperature being raised to full redness, the current of gas being still maintained, the whole is gradually converted into an orange-yellow powder, unalterable at all normal temperatures, and producing evidence of the formation of ammonia after the addition of sodium hydrate to an acidified solution of the same. It also not unfrequently happens, on dislodging the coils of magnesium that have been sustained at a dull red heat only, when under the influence of the ammonia gas, that small quantities of the ribbon thus employed have assumed a deep yellow colour, and of a lustre equal to that of gold. This peculiar substance, whether indicative

of an allotropic modification, or the formation of a nitride, is as yet impossible to state, owing chiefly to the uncertainty of producing the same. From several observations, however, I am of opinion that traces of aqueous vapour tend to favour its formation.

18, Albion Street, Everton, Liverpool.

NEW METHOD OF DETERMINING CARBONIC ACID IN SOLUTION.

By LEO VIGNON.

CARBONIC acid in an aqueous solution, whether free or combined with the neutral carbonates, rapidly decolourises the red liquid formed by mixing 50 c.c. of lime-water and 10 drops of a saturated alcoholic solution of pure phenolphthalein. Hence it results that carbonic acid dissolved in water, free or in a state of semi-combination, can be determined volumetrically by means of a standard solution of calcium hydroxide, using, under suitable conditions, phenolphthalein as an indicator.

The details of the process are as follows:—50 c.c. of the water in which the carbonic acid is to be determined are mixed with 0.05 c.c. (10 drops) of a saturated alcoholic solution of phenolphthalein, and there is gradually added to the liquid lime-water which has been previously standardised (by means of decinormal sulphuric acid and cochineal) until it takes and retains the rose shade which is characteristic of phenolphthalein in presence of an excess of lime. In order to obtain constant results, it is necessary to compare the final tint with that of a liquid of the same composition as the water to be examined, but perfectly free from carbonic acid. As a type there may be used either water recently distilled, or a portion of the water under examination, which has been boiled long enough to expel all carbonic acid.

Fifty c.c. of each of these two liquids, raised to the same temperature, are placed in two test-glasses on feet, graduated, having ground glass stoppers, and not exceeding 2 or 3 c.m. in diameter. Into each glass are put 10 drops of the alcoholic solution of phenolphthalein, and we then begin to colour slightly the type liquid with a measured quantity of standardised lime-water added from a burette graduated in tenths of a c.c. without reaching the maximum colouration which can be produced. 0.2 to 0.5 c.c. will mostly suffice.

The solution of lime is then gradually added to the water under examination. The colour produced by the contact of the lime-water disappears very rapidly on agitation at the beginning, so long as carbonic acid is found in the liquid in sufficient excess. Towards the end of the reaction the combination of the lime with the carbonic acid takes place more slowly; it is therefore convenient to agitate the liquid frequently and to add the lime-water at longer intervals. Care must be taken not to let the colour in the water in question exceed the intensity of colour of the type. When the colouration of the sample no longer varies, which occurs after an hour, if the precaution has been taken to agitate frequently, the type is made up to the same volume as the water to be examined, and an identity of shade between them is effected by adding lime-water to that which is palest.

The two glasses are used like the tubes of a colorimeter. On examining them against a white ground we may, with a little practice, detect the shades of colour due to the addition of 0.1 c.c. of lime-water. When the colours are identical we know that the two liquids contain the same quantities of free lime. The difference between the lime consumed by the water under examination and that which has served to colour the type corresponds to the carbonic acid sought for.

The presence of calcium and magnesium chlorides, sulphates, and nitrates does not affect the results. Calcium

carbonate, indeed, colours phenolphthalein slightly, but, besides that this colouration is not comparable in intensity to that yielded by free lime, it is not manifested in presence of carbonic acid.

If the water contains alkaline salts, the acids of which are capable of forming insoluble salts of calcium or magnesium carbonate, which is slightly alkaline before titration, a little neutral calcium chloride must be added to convert the magnesium carbonate and the alkaline salts into chlorides. This peculiarity may be detected by the colour which the water, after being boiled in a platinum capsule, will take with phenolphthalein.

If the water contains much carbonic acid the calcium carbonate renders the liquid opaque, and does not permit of a colorimetric comparison with the type. This inconvenience may be remedied by adding to the coloured type a little pure calcium carbonate, or by letting the calcium carbonate in the sample under examination have time to settle.—*Bulletin de la Soc. Chimique de Paris* (vol. xlix., p. 903).

PROCEEDINGS OF SOCIETIES.

THE ROYAL SOCIETY.

Anniversary Meeting, November 30th, 1888.

ADDRESS OF THE PRESIDENT, PROF. G. G. STOKES.

IN the month which intervened between our last anniversary and the end of the year, the Society lost four of its Fellows. In addressing the Fellows last year, I referred to the loss which science had sustained through the death of the illustrious Kirchhoff, and before three weeks were out, one followed him to the grave whose researches on the connection between the emission and absorption of radiant heat and light were closely akin to those of Kirchhoff. I refer to Balfour Stewart, who, shortly after landing in Ireland, whither he had gone to spend the Christmas with his family, was suddenly carried off after only a few hours' illness, shortly after he had entered on his sixtieth year. His name is widely known on account of his scientific work in heat, magnetism, and solar physics. He has been a member of the Council, and the Rumford Medal of the Society was awarded to him for the particular research to which I alluded at the outset. The other three of our ordinary Fellows who died before the month was out were all far advanced in years. Two of them were eminent in the medical world, Sir George Burrows and Dr. Arthur Farre, both of whom served on our Council. Early in the year we lost one of our Fellows, who, while not a man of science, was eminent in literature and jurisprudence. While our ranks are mainly recruited from men of science, we gladly welcome among us men who, like Sir Henry Sumner Maine, have proved their ability and earned their distinction in other branches of knowledge; whose connection with us we look on as honourable to the Society, while, as the very fact of their joining us shows, they regard the Fellowship as honourable to themselves. Admiral Sir Cooper Key, who was highly distinguished as a naval officer, and was at one time Director of the Royal Naval College at Greenwich, was another who served on the Council. Philip Henry Gosse, who died at an advanced age, is well known for his charming popular works on natural history. These are some of the Fellows on the home list who died since the last anniversary; but besides these we have lost no less than three of our foreign members. Prof. Anton de Bary, so well known for his researches on the Cryptogams, and the eminent naturalist, Prof. Asa Gray, who not very long ago was over in this country, both died in January. Comparatively recently we have lost Prof. Clausius, so eminent as a physicist, especially in the department of thermodynamics.

The year of the Society which terminates to-day has shown no flagging in scientific activity. Since the last anniversary thirty-three memoirs have been published in the *Philosophical Transactions*, containing a total of 1010 pages and 91 plates. Of the *Proceedings*, 19 numbers have been issued, containing 1008 pages and 17 plates. In addition to this, a monograph of the "Horny Sponges of Australia," by Dr. R. von Lendenfeld, which was accepted for publication by the Council, and which when completed will extend to about 1000 pages, is now nearly through the press.

A large amount of work connected with the Library has been done since the last anniversary. A special effort has been made to complete imperfect series of scientific periodicals; and by means of exchange, or by the generosity of our corresponding societies, some hundreds of deficient numbers have been obtained. The lists of Institutions entitled to receive gratis the *Philosophical Transactions* and *Proceedings* have also been carefully revised by the Library Committee.

In December last Mr. Arthur Soper was engaged as a special Assistant to continue the formation of the Shelf-Catalogue, and the revision of the Catalogue of MSS., and other work. The Shelf-Catalogue of the Upper Library is now completed—a work involving the rearrangement or removal to the lower stories of several thousands of volumes. Considerable progress has been made in collating and cataloguing the Archives and other manuscripts belonging to the Society, and an instalment of slips have been written towards a Catalogue of the Miscellaneous Literature in the Library.

In the course of this work many duplicate scientific books, and literary works of little value to the Society, have been thrown out, and these have been presented by order of the Council to the libraries of the Universities and some of the chief scientific Societies.

The cataloguing of the titles of scientific papers for the decade 1874 to 1883 is now complete, and the work is ready for the press. The amount of matter is estimated to require, if printed, three quarto volumes of the usual size. The extraction of the title, the preparation of the work for the press, and the correction of the proofs of this work, which is really of international importance, has all along been done at the sole charge of the Royal Society; but the printing of the volumes which have already been published has been done at the Stationery Office by the authority of the Lords of the Treasury, and the proceeds of the sale have been paid in to the Treasury. The Council have applied to the Lords Commissioners of Her Majesty's Treasury to sanction the printing of the last decade in a similar manner, and it is hoped that the application may be favourably entertained.

In the year 1882 a change was made in the amount and mode of administration of the grant which for a considerable time before had been voted annually by Parliament for scientific research. Since that year the annual grant has been one of £4000, which has been administered by the former Government Grant Committee, with the addition of certain *ex-officio* members, mostly the Presidents of certain scientific Societies. Meetings of this large Committee, consisting usually of about fifty members, have been held twice a year, and the various applications for aid from the grant to enable the applicant to carry out investigations explained by him, have been previously discussed in meetings of three, or latterly two, Sub-Committees, into which the whole Committee was divided, and then submitted to the General Committee for confirmation or modification.

In the discussion of these grants, the Government received the benefit of the gratuitous services of a large number of men of the highest distinction in science. In the large Sub-Committees, however, it necessarily happened that of the members present only a fraction would be likely to be conversant with the particular branch of science to which any particular application belonged; and the Council thought that the time of the members

might be economised, and at the same time a more efficient discussion of the grants secured, by arranging the applications under a number of sub-divisions, and assigning the discussion of these to a corresponding number of Boards formed out of the General Committee. It was thought that a good deal of the discussion of the applications in the several branches might be carried on by correspondence among the members of the respective Boards, so that one or two meetings of each Board might suffice. If some trouble were thus saved to the members of the Committee in regard to personal attendance at long meetings, there would probably be more expenditure of time in the way of correspondence, and it was thought that one meeting of the General Committee in the year would in most cases suffice. To meet pressing cases in the interval, it was suggested that a limited sum might be placed by the General Committee at the disposal of the Council of the Royal Society. There are further provisions for forming a reserve fund of not more than £2000 to meet special objects involving unusual expenditure, and for holding in reserve out of the money available for any one year enough to meet annual grants of limited amount made for a period not exceeding three years, the future grants being contingent on the receipt by the Committee of satisfactory evidence of progress in the inquiry. The new regulations, of which I have merely given a slight sketch, have been communicated to the Treasury, and will come into operation next year.

The Krakatao Committee have now completed their work, and the volume which is the outcome of their labours is in the hands of the public. The society is much indebted to those Fellows and other gentlemen who discussed and reported on the different subjects into which the whole inquiry was divided, and to Mr. Symons, who was the first to propose that the materials should be collected, and to whose unwearied labour as Chairman of the Committee, director of the correspondence, and editor of the volume, the successful accomplishment of the undertaking is largely due. The work has been favourably noticed in more than one quarter. A comprehensive and digested account of that extraordinary volcanic explosion, remarkable both for its magnitude and the striking disturbances and other phenomena attending or following it, is now placed within easy reach of the ordinary reader, and will go down to posterity; whereas, had the various accounts remained in their isolated form, they would many of them have perished, and the remainder could not have been brought together without a most laborious search. It must be a great satisfaction to my predecessor in this chair to remember that he urged upon the Council the importance of collecting the facts before the materials should have become dissipated, and while the freshness of men's recollection of the event kept up a lively interest in all that belonged to it.

The Royal Society is in possession of some important standards for the safe keeping of which we are responsible. Parliamentary copies of the standard yard and standard pound have been intrusted to our custody; and we have also a standard measure of length known as Sir George Schuckburg's scale, with reference to which the length of the seconds pendulum for Greenwich has been determined by Kater and Sabine. This length, as determined by experiment, has been defined with reference to the interval from the 0 to the 39- and 40-inch graduations on the scale; but no exact comparison has hitherto been made between the length of this portion of the scale and the national yard, and such a comparison is no easy matter. It happens that Commandant Deforges has been engaged in determining the length of the seconds pendulum at Greenwich with reference to the French standard metre, and just before his return to Paris he came to our meeting and offered to take charge of the scale, bring it with him to Paris, and there determine the length of the part of the scale used by Kater and Sabine with reference to the metre, for doing which he has all the requisite appliances; and as we know the ratio of the metre to the yard, the

length of the seconds pendulum, as determined by Kater and Sabine, would thus be known accurately with reference to the standard yard. It seemed to me that so important a scale should hardly be sent away, even though in the care of so experienced a physicist, without the authority of the Council, and without an outer case being made for its box, which there was no time to get ready. The authority of the Council has since been obtained, and it fortunately happens that one of the assistants at the Greenwich Observatory is going to Paris who will take charge of the scale. Thus by the kind proposal of Commandant Deforges we may shortly hope to have an authentic comparison of the length of the seconds pendulum as measured by Kater and Sabine with the standard English yard.

At the time of the anniversary last year, some of the reports of the observers who went to Grenada to observe the total solar eclipse of August, 1886, had been sent in, and I mentioned that it seemed desirable, for convenience of reference at a future time, that the different reports should come out together, instead of being published in a scattered form, provided at least that the waiting for the later reports should not cause too much delay. I regret to say that the completion of the reports has been delayed in part by the illness of one of the observers, but I have every hope that they will all be in by Christmas, and I do not anticipate that any long time will elapse before they will be in some form in the hands of the public.

The time is well within our recollection when the occurrence of the solar prominences seen in total eclipses first attracted the attention of astronomers, and when for observations bearing on their nature we had to wait for the rare and brief glimpses which, clouds permitting, were afforded by total eclipses. Now, however, thanks to the method of observation devised independently by Lockyer and Janssen, they may be studied at any time. It would obviously be a great advantage if a similar study could be made of the corona; for though we cannot expect to obtain a picture of it equal to that which may be got during a total eclipse, yet, if a fairly good picture could be obtained from time to time, we might thereby be enabled to learn more about the history of its changes than could be got by observations extending over a lifetime if restricted to total eclipses. Some observations were made during the partial phases of the last total eclipse with the view of throwing light on the prospect of success. Notwithstanding the unpromising nature of the results obtained, I have reason for hoping that the desired object may yet be accomplished.

In addressing you last year, that year which will be memorable as the Jubilee of the reign of our beloved Sovereign, I alluded briefly to the progress which science had made in the last half-century, and ventured to indicate one or two directions in which it seemed to me possible that a very great addition to our physical knowledge might some day be reached. I will not to-day venture to look so far ahead; but the mention of a total eclipse leads me to refer to some theories now before the scientific world which are likely to undergo full discussion and further examination in the near future, with the probable result of a pretty general agreement as to their acceptance or rejection.

It is now many years since Dr. Huggins discovered the peculiar character of the spectra of the nebulae, spectra which he found to consist mainly of bright lines, indicating that what we see is an incandescent gas. The natural supposition to make at the time was that those distant masses of matter consisted of incandescent gas, of which the luminosity was in some way kept up, probably as a result of condensation. But the researches of Mr. Lockyer, as described by him in the Bakerian Lecture which he delivered last spring, and in part in a previous paper communicated shortly before the last anniversary, have led him to take a different view of the constitution of nebulae. According to the theory advanced by him, the mass of a nebula consists mainly of meteorites, which

are constantly coming into collision here and there; and the glowing gas the existence of which the spectroscopic reveals, is merely a portion of the matter, volatilised by the heat of collision. According to the former view, therefore, the nebula consists of glowing gas, not yet condensed into a solid or liquid form, possibly in a condition even more elementary than that of the so-called elements that we know on earth; according to the latter it consists mainly of discrete portions of solid matter, and the glowing gas does not consist of the same matter permanently glowing, but is continually supplied afresh by fresh collisions.

A similar theory is applied to explain the self-luminosity of the nucleus, and sometimes the very root of the tail, of comets. A comet is regarded as a swarm of meteorites, moving in orbits not greatly differing from one another; and as the swarm approaches the sun collisions become more frequent, and individually more potent, from an increase in the velocities, differential as well as absolute; and a portion of matter is volatilised and rendered incandescent. As to the tail, the theory long ago suggested by Sir John Herschel has always seemed to me by far the most probable of those that have been advanced—namely, that it is due to the propulsion of excessively attenuated matter, owing to a repulsive force, probably of electrical origin, emanating from the sun. This view seems to be adopted both by Mr. Lockyer and Dr. Huggins; and the latter gentleman, in an earlier Bakerian Lecture, has suggested a new theory of the corona—the corona as distinguished from the prominences—namely, that it is not projected from the sun by molar forces due to the tremendous state of turmoil in which we have very strong reason for believing that the matter composing the sun exists, but of matter actually propelled from the sun by a repulsive force in the manner of the tails of comets.

Daring as some of these speculations may appear to be, there seems a great deal to recommend them, and the whole subject is one of extreme interest at the present day.

But I must not take up your time longer by dwelling on so special a subject; I proceed to matters more particularly connected with the occasion on which we are assembled.

The Council have awarded the Copley Medal of the year to my predecessor in this Chair, Mr. Huxley, for his investigations on the morphology and histology of vertebrate and invertebrate animals, and for his services to biological science in general, during many past years. These subjects lie so entirely out of the range of my own studies that I need hardly say that in attempting to give some idea of the more salient features of his investigations I am dependent upon the kindness of biological friends.

During the fifteen or twenty years which preceded the publication of Darwin's famous work, the "Origin of Species," the views and methods of comparative anatomists underwent a most marked change. Without the change, biologists would have been far less prepared to accept Mr. Darwin's work, and, what is even more important, would have been unprepared to make use of that work as a light enabling them to carry on the remarkable researches which have so brilliantly characterised the progress of biology during the last quarter of a century. That change was effected chiefly by the labours first of Johannes Müller, and subsequently of Huxley in this country, and of Gegenbaur in Germany. The labours of these men opened out the right road of morphological inquiry. It is not, perhaps, too much to say that Mr. Huxley's treatment of his subject in his "Morphology of Cephalous Mollusca" was to many young morphologists little short of a revelation, and all his other works of the same period, such as that on the Hydrozoa and on Tunicates, and, later still, his treatment of the Vertebrate skull and skeleton, and Arthropoda, produced in varying degree a like effect.

Closely allied to, or rather forming part of, his morphological labours, are his numerous palæontological re-

searches, carried out for the most part while he was Palæontologist to the Geological Survey, researches characterised by the same clear morphological insight, researches which have been as profitable to animal morphology as useful to the geologist. The most important are perhaps those on the remarkable reptiles of the Elgin Sandstones and on the Dinosauria; but many others have great value, and his anniversary address to the Geological Society, in 1870, made its mark.

Though his career has been in the main that of a morphologist, he has through the common ground of histology given considerable help to physiology. An early paper by him "On the Cell-Theory," did much to clear away erroneous notions concerning the relations of structure to the actions of living beings. His article on "Tegumentary Organs" was a great step onward as regards both morphology and histology, and still remains a classical work; while, by other papers and in various ways, he has contributed to the progress of histology and physiology.

But, however important Mr. Huxley's original contributions to the advancement of our scientific knowledge have been, we should form a very inadequate idea of his benefits to the cause of science if we did not bear in mind also his singular ability and effectiveness as an expositor of science to the people, and the powerful influence he has exerted in the improvement of the teaching of biology in its widest sense in this country. Indeed, it is not too much to say that the remarkable improvement which has taken place within the last few years must be ascribed either directly or indirectly to his influence, and has been in many cases due to his initiation.

The Rumford Medal has been awarded to Prof. Pietro Tacchini for important and long-continued investigations, which have largely advanced our knowledge of the physics of the sun.

Prof. Tacchini occupies a foremost place among those who have paid special attention to the physics of the sun. Since 1870 he has unceasingly observed, first at Palermo, and afterwards at Rome, the solar prominences. The information at our disposal at the present time, both as regards their distribution, their spectra, and the changes which take place in them, and their connection with other solar phenomena, rests to a large extent upon his individual efforts. His memoirs on this subject are very numerous. He has been engaged in the observation of four total solar eclipses, and from some of the phenomena therein observed has drawn the important conclusion that many of the so-called prominences are really descending currents.

A Royal Medal has been awarded to Sir Ferdinand von Mueller for his long services in Australian exploration, and for his investigations of the flora of the Australian continent.

For more than forty years von Mueller has been working, without intermission, at scientific botany and its practical illustrations. As a botanical traveller and collector, he has, to quote the words of Sir Joseph Hooker, "personally explored more of the Australian continent than any other botanist, except Allan Cunningham." No one has investigated the Australian flora and the geographical distribution of its components with so much perseverance and success, and no one has enriched our herbaria, laboratories, and gardens with materials for study to so great an extent. The eleven volumes of the "Fragmenta Phytographiæ Australiæ" contain the descriptions of a great series of new plants, and the unrestricted communication of his collections and observations to the late Mr. Bentham rendered possible the preparation of the "Flora Australiensis," in seven volumes, the only account of the vegetation of any large continental area which has at present been completed.

He has especially devoted himself to the elucidation of the most difficult though most characteristic groups of the Australian flora; and as a result of his labours in this direction, his "Eucalypto graphia" may be more particularly mentioned, a work which will always be the

standard of nomenclature for the intricate genus *Eucalyptus*. Of a similar character are his descriptions and illustrations of the "Myoporineous Plants of Australia," and his Iconography of the Genus *Acacia*." To him is also due the foundation of the Government Herbarium at Melbourne, the first great botanical collection formed in the southern hemisphere, and the future centre of all scientific work on the Australasian flora.

A Royal Medal has been awarded to Prof. Osborne Reynolds for his investigations in mathematical and experimental physics, and on the application of scientific theory to engineering.

Prof. Reynolds was among the first to refer the repulsion exhibited in that remarkable instrument of Mr. Crookes's, the radiometer, to a change in the molecular impact of the rarefied gas consequent upon the slight change of temperature of the movable body due to the radiation incident upon it; and in an important paper published in the *Philosophical Transactions* for 1879, he deduced from theoretical considerations the conclusion that similar phenomena might be expected to be observed in bodies surrounded by a gas of comparatively large density, provided that surfaces were very small. He verified this anticipation by producing on silk fibres, surrounded by hydrogen at the atmospheric pressure, impulsions similar to those which in a high vacuum affect the relatively large discs of the radiometer.

In an important paper published in the *Philosophical Transactions* for 1883, he has given an account of an investigation, both theoretical and experimental, of the circumstances which determine whether the motion of water shall be direct or sinuous, or, in other words, regular and stable, or else eddying and unstable. The dimensions of the terms in the equations of motion of a fluid when viscosity is taken into account involve, as had been pointed out, the conditions of dynamical similarity in geometrically similar systems in which the motion is regular; but when the motion becomes eddying it seemed no longer to be amenable to mathematical treatment. But Prof. Reynolds has shown that the same conditions of similarity hold good, as to the average effect, even when the motion is of the eddying kind; and moreover that if in one system the motion is on the border between steady and eddying, in another system it will also be on the border, provided the system satisfies the above conditions of dynamical as well as geometrical similarity. This is a matter of great practical importance, because the resistance to the flow of water in channels and conduits usually depends mainly on the formation of eddies; and though we cannot determine mathematically the actual resistance, yet the application of the above proposition leads to a formula for the flow, in which there is a most material reduction in the number of constants for the determination of which we are obliged to have recourse to experiment.

There are various other investigations of Prof. Reynolds's which time would not allow me to enter into, and I therefore merely mention his investigation of the relation between rolling friction and the distortion produced by the rolling body on the surface on which it rests, that of the effect of the change of temperature with height above the surface of the ground on the audibility of sounds, and his explanation of the effect of lubrication as depending on the viscosity of the lubricant.

The Davy Medal has been awarded to Mr. Crookes for his investigations on the behaviour of substances under the influence of the electric discharge in a high vacuum.

Mr. Crookes's remarkable series of researches which conducted him to the invention of the radiometer led him to work with excessively high vacua. In connection with this he found that an electric discharge in such vacua is capable of exciting effects of phosphorescence apparently quite different in their origin from those produced in the ordinary way by such discharges. The latter are clearly referable to the action of the ethereal undulations which are propagated from the seat of the discharge. But

the former involve in some way the effect of the actual transference of the molecules of ponderable matter. These phenomena in the hands of Mr. Crookes opened up a new means of discrimination between different bodies, and he has applied them as a test for the discrimination of groups of rare earths, not yet fully investigated. The test went hand in hand with processes of chemical separation. But here a great difficulty presented itself. So very closely allied in their chemical properties are the members of the groups, that it was only by an excessively tedious and laborious system of fractional precipitation that Mr. Crookes was able to effect a pretty fair separation; even still, the separate existence of some members of the groups is more or less problematical. It is for these painstaking researches that the medal has been awarded.

The existence, or apparent existence, of so many earths of such close chemical relationship led Mr. Crookes to speculate on the possibility that after all the molecules of what is deemed a chemical element may not be absolutely alike, as chemists have almost universally believed, but only very approximately so, and that what is deemed the molecular weight of the substance may really be that of the average of its molecules. Should such groups exist, it is conceivable that by processes of very delicate chemical separation they might be split up again into sub-groups, the molecules of which still more nearly match one another; so that according to this view the number of groups into which an element, or what is deemed such, might be split up, not, be it observed, by any dissociation, but merely by a sorting of the molecules which are very nearly alike, may be somewhat indefinite.

Chemists will not probably be disposed to give up the idea of the perfect similarity of the individual molecules of elementary bodies; but it is surely legitimate for one who has worked so assiduously at these difficult separations to suggest, merely as a matter for chemists to think about, a possible view of the nature of elements different from that to which they have been accustomed.

PRESENTATION OF A PORTRAIT OF PROFESSOR A. W. WILLIAMSON, F.R.S., TO UNIVERSITY COLLEGE.

ON Wednesday (12th instant) a portrait of Prof. A. W. Williamson, late Professor of Chemistry in University College, London, was presented to the College by Sir Henry E. Roscoe, M.P., F.R.S., on behalf of the committee of subscribers. The portrait is painted in oil by the Hon. John Collier.

The presentation took place in one of the lecture rooms, the Chair being taken by the President of the College (Mr. John Erichsen, F.R.S.), and amongst those present were Sir F. A. Abel, Prof. Bonney, Prof. H. Morley, Dr. J. H. Gladstone, Prof. George Carey Foster, Dr. Atkinson, Prof. Ramsay, Prof. Thorpe, Prof. Marks, Prof. Russell Reynolds, and other professors, and a large number of the past and present students of the College.

Dr. W. J. RUSSELL, on behalf of the Committee, for whom he had acted as Treasurer, said—Judging from the subscription list, there was a large number of the former colleagues of Prof. Williamson who had subscribed to this portrait, and it would no doubt be very pleasant to him to know that members of all the chemical societies in England had liberally subscribed towards the portrait, and further, that many of the subscribers had not satisfied themselves by sending formal contributions, but had written to him (Dr. Russell) expressing their great esteem and regard for Dr. Williamson. The subscriptions not only came from all parts of Great Britain, but from France, Germany, Switzerland, Italy, Russia, and even so far afield as the United States, Jamaica, India, and Japan. He thought this was all that it was necessary for him to say in order to indicate the high value which the

subscribers attached to the great scientific attainments and labours of Dr. Williamson, whose intimate friends and old pupils, who knew him best, now came forward to pay him this mark of their esteem and regard.

Sir HENRY ROSCOE—I consider it, Sir, a privilege that, as an old pupil and an attached friend of Dr. Williamson, I should have been chosen on this occasion to present his portrait—which I think you will all consider as a life-like one—by Collier, to the College in which he laboured so faithfully and so successfully for nearly forty years. The first appointment of Dr. Williamson dates, as you, Sir, are aware, from the year 1848, when, following Fownes, he was, as Professor of Practical Chemistry, placed in charge of the first teaching scientific laboratory established in England, and in a few years afterwards, on the resignation of Graham, he assumed the responsibility of the two Chairs of Chemistry. A favourite pupil of Liebig's, Williamson had, at Giessen, imbibed the scientific spirit of that great master, and had, at the early age of nineteen, published his first original investigation. Afterwards carrying on his studies in Paris, and becoming intimate with Laurent and Gerhardt, he brought to London the best traditions of the French as well as of the German schools of chemistry, uniting in his person the attributes of both. Entering upon his duties in this college with the enthusiasm for his science characteristic of his nation, was it to be wondered at that he should have imparted to the young men fortunate enough to have come under his influence some sparks of that fire which burnt so brightly in his own breast? I well remember the vivid interest, the keen appreciation, with which all those who studied in the Birkbeck Laboratory at that now distant time followed, step by step, the unfolding of his views on etherification and on the constitution of salts, which may truly be said to have laid the foundation of modern organic chemistry. All those of his pupils who then made up their minds to devote their lives to chemistry, whether in the walks of the pure science or in those of its applications, must willingly own that much of the success which they may have met with in after years is due to his teaching and example, and admit that in the receptive period of a man's life the influence exerted upon them by a teacher whose years were not far removed from their own, of high aims and of ardent temperament, could not fail to be inspiring. This is not the occasion to enquire into the position which Williamson holds as one of the great chemists of our time and country. Rather is it our object now to express the feelings of gratitude, and if I may be allowed to say so, of affection, which we who have been his pupils, and are his friends, as well as those of us who can only claim the latter but perhaps no less intimate relationship, entertain towards him. To assure him that we look back upon the times spent in personal contact with him as some of the pleasantest as well as some of the most fruitful of our lives. And both pupils and friends here join to show their appreciation of his labours and of his character, and to acknowledge the debt which they and their science owe to him. This portrait, Sir, of our friend and master finds a fitting resting-place in the halls of the college in which his working years were spent. It will remain as a memorial of a teacher, an investigator, and a colleague whose main interest was to uphold and increase the renown of University College as a centre of intellectual progress, and of one whose character, both as a man and as a chemist, future generations, like our own, will delight to honour. It is now my pleasing duty to unveil the portrait, and to ask you, Sir, as the President of this College, to accept it on behalf of the subscribers.

The portrait was then exposed to view.

The PRESIDENT—In the name of and on behalf of the Council and Members of this College I accept with gratitude this admirable likeness of our dear colleague and friend, Dr. Williamson. Sir Henry Roscoe has truly said that this is not the place to dilate on Dr. Williamson's great scientific merit, and the great claims which he has

as a scientific man to any honour that could be bestowed upon him. I shall not venture on this subject, but I may say this: that, looking at Dr. Williamson's career, as I can do for the last forty years—thirty years of which he has been connected with this college, ten years as a governor—there never was a man more loyal to this institution and more devoted to its best interests than Dr. Williamson. The business of a Professor is here not only to teach but to take part in the management of the college, which, as you know, devolves individually and collectively upon them. It is in the meetings of the Council of the Senate that the devotion of the Professors to the interests of the College is shown quite as much as in the teaching of his classes. The College could not be worked without the business aptitude of the professorial staff, and in this duty of management none showed more zeal, loyalty, and devotion during thirty years than Dr. Williamson. We, as a governing body, must feel deeply indebted to him for the interest which he has shown in the welfare of this institution. But I should not be doing my duty if I were not to couple with his name that of his wife. Mrs. Williamson was as devoted as her husband, and did very much to raise the character of the school. She showed the greatest interest and enthusiasm in all the work which, as a woman, she was able to perform, and bring about harmony within the walls of this institution. Mrs. Williamson worked, side by side with her husband, with unwearied devotion in, as I have already said, the best interests of University College. Ladies and gentlemen, I can only add in my own name and in the name of this institution, the hope that Dr. and Mrs. Williamson will be followed with all health and happiness in their comparative retirement from further active work.

Sir FREDERICK ABEL—Allow me to move a vote of thanks to the President of the College for his kindness in being the mouthpiece of many old friends in expressing as he has done the high respect and great affection entertained for Dr. Williamson by all his old colleagues. I desire to add that it is a great pleasure to me to be able to assist at this ceremony, and I for one am highly gratified at the lifelike portrait presented to the College, and accepted by you, Sir, as President on its behalf.

Dr. T. ANDERSON—As an old pupil of, and as an old dresser to, the President I have great pleasure in seconding the vote of thanks proposed by Sir Frederick Abel.

The PRESIDENT briefly acknowledged the compliment which had been paid him.

Dr. WILLIAMSON (who was received with cheers) said—I believe, Sir, that the reward which, upon the whole, is the most satisfactory (and which, perhaps, I may call the highest) which can be given to the man who has endeavoured to do his duty is the expression of approbation from men of high authority on the subject-matter on which he has worked. The compliments which have been paid to me to-day have been enhanced greatly by some words which Sir Henry Roscoe let fall, and which could not have come with greater weight from anyone than from my old friend. It is to me a proud feeling—one which gives me great satisfaction—that in the decline of my life and in the end of my career I should from such a man—a man of such high character and position—have received so cordial and friendly an expression of approbation and personal esteem. I must ask leave, Sir, to thank the Council and you as their head for the honour which you have done me in allowing my portrait to be placed within these walls, for, although I have been associated with other colleagues and have performed duties of other kinds, there is no place that I have felt it so great an honour to be connected with as University College, where I have been associated with so many men who have made noble, self-sacrificing efforts in the best interests of this institution. I look back with pride on my connection with my colleagues of this College, though I have often bitterly regretted that my intercourse with the students has not been more personal. Sometimes a man comes up to me, shakes me by the hand, and calls me by name, and I am

obliged, to my shame, to confess that I do not know his name, which I am obliged to ask, and then I find he was an old student who knew me perfectly, remembered me lecturing in a long, dark room, in which I was visible to him though he was not visible to me. I have often very much regretted that I have not been brought into closer relations with this large body of earnest men and students. Still among those I have known I have found many esteemed friends. I do not think it desirable for me to make further remarks at present beyond expressing to Mr. Collier my appreciation of his success in making what is not an ugly portrait out of such an ugly face as mine.

The proceedings then terminated.

In the Evening, at the Freemason's Tavern, Dr. Williamson was entertained at Dinner by a goodly number of his pupils and friends. Sir HENRY ROSCOE, M.P., F.R.S., presided.

After the toast of "The Queen" had been given and duly honoured, Mr. CARTEIGHE, one of the Honorary Secretaries, announced that a considerable number of letters from subscribers had been received expressing their regret at not being able to be present. The one from Prof. Michael Foster, F.R.S., referred humourously to Dr. Williamson as the "Ether Meister."

Sir H. ROSCOE, in proposing the toast of the evening, "Our Guest, Dr. Williamson," referred in kindly and affectionate terms to his early association with him, to his enthusiasm as a teacher, and the influence which it exerted on all his pupils, and to the respect entertained for Dr. Williamson by men of science in all parts of the world.

Dr. WILLIAMSON, in reply, expressed the gratification which this Dinner had afforded him, and referred with pride and satisfaction to the great honour which had been conferred upon him in the presentation of his Portrait to University College. In conclusion he wished any of his old pupils, present or absent at that gathering, when in the neighbourhood of Hindhead, to call and see him in his "nest."

Professor NORMAN LOCKYER, F.R.S., proposed "University College and its President," and expressed his admiration at the excellence of the work in Science and Literature which had been carried out in that institution and the influence the College was exerting on scientific education.

Mr. BRICHSEN, F.R.S., President of University College, responded to the toast.

Professor W. H. FLOWER, F.R.S., proposed the health of the Professors of University College, and referred to the long roll of distinguished men who had filled Chairs in the College. He complimented the existing staff on their thoroughness and earnestness.

Professor HENRY MORLEY responded for the Arts Faculty and Professor G. C. FOSTER, F.R.S., for that of Science.

Professor RAMSAY, F.R.S., proposed "The Chairman," to which toast Sir Henry Roscoe replied.

Professor T. E. THORPE, F.R.S., proposed "The Committee of the Williamson Testimonial," to which Mr. Michael Carteghe, President of the Pharmaceutical Society, and Dr. H. Forster Morley, the Honorary Secretaries, responded.

The entertainment concluded with a charming musical sketch given by Professor Ramsay, at the request of the Chairman.

On the Benzoic Acetals of Mannite and its Homologues: Decomposing Action of Benzoic Aldehyd.—J. Meunier.—When a benzoic acetal (and the same doubtless holds good for other acetals) is completely freed from the excess of aldehyd to which it owes its origin, it resists the action both of acids and alkalis; it is not decomposed by prolonged boiling with acidulated water, but if the aldehyd is present it is very rapidly decomposed on boiling.—*Comptes Rendus*, Vol. cvii., No. 23.

NOTICES OF BOOKS.

The Art of Dispensing: A Treatise on the Methods and Processes involved in Compounding Medical Prescriptions. Second Edition. London: Offices of the *Chemist and Druggist*.

MANY of the directions here given will be regarded as matters of course by all persons familiar with chemical analysis or research. But the pharmacist has special demands to meet and difficulties to encounter, for which he must be well prepared, and to these points due attention is called in the work before us. Such are, *e.g.*, the neatness and the distinctness of labels, for which the type-writer is pronounced useful, and might, indeed, have a good claim to exclusive adoption.

A chapter on prescribers and dispensers discusses the questions of ambiguous nomenclature, from which surely the language of pharmacy ought to be free; the question of measurement; the graduation of medicine-bottles, the accuracy of which is not accepted; careless prescribers who have no rightful *raison d'être* and extra doses. The German law demands in this case the addition of the mark (!) to any unusual quantity. If this caution is omitted the consequences are visited not upon the prescriber but upon the dispenser. Of two cases here quoted, in the former the prescriber had omitted the mark, but had, instead, several times underlined the extra dose, potassium cyanide. On the death of the patient the pharmacist was condemned to a year's imprisonment. In another case the prescriber meant to order 4 grms. of chloral hydrate, but instead of 4.0 grms. he omitted the decimal point and wrote 40. In this case also, which gives an instance of the dangers of decimals in such matters as prescriptions, the pharmacist suffered a long imprisonment.

The dangers of making up prescriptions with spring or well-waters, and the changes which such a practice may produce, at least in the appearance of the medicine, are duly noticed.

A chapter is given on "Incompatibles," which sometimes manifest their mutual disagreement to the extent of a dangerous explosion, and show the necessity for the pharmacist of a very thorough knowledge of the possible reactions of all medicinal substances. We find an instance given of a prescription which resulted in the formation of nitrogen iodide!

Dispensing foreign—especially German—prescriptions must be a tribulation. In addition to the peculiar nomenclature which physicians and "apotheker" still indulge in, in which chlorides and iodides respectively figure as chlorates and iodates, there is the Gothic script. Of one prescription here reproduced in *fac simile* the author says:—"This prescriber looks like taking first prize for bad writing."

But the specimens of English prescriptions here given rank high in illegibility, and it is time that either public opinion or law should here step in. When a physician writes out prescriptions in his own consulting-room he would do well to have a type-writer at hand.

In this last section we regret to find the absurd term "caligraphy" twice used for "handwriting." The author should remember that caligraphy means ornamental writing, as distinct from and often opposed to that which is simply legible. If a synonym is wanted for handwriting why not say cheirography?

We are happy to say that this neologism, "caligraphy," is the only flaw which we find in an exceedingly useful and ably-written book.

Transformation of Terpine into a Menthene.—G. Bouchardat and J. Lafont.—Natural menthol must be connected with the terpene series. Menthol, $C_{10}H_{18}O_2$, has relations of composition with terpinol or terpene monohydrate, $C_{10}H_{18}O_2$, similar to those which exist between the allylic and propylic alcohols.—C. R., No. 23.

CORRESPONDENCE.

ULTRA VIOLET SPECTRA OF THE ELEMENTS.

To the Editor of the Chemical News.

SIR,—The recent contribution of Messrs. Trowbridge and W. C. Sabine, which appeared in the *CHEMICAL NEWS* (vol. lvi., p. 247), entitled "Wave-Lengths of Metallic Spectra in the Ultra Violet," is one of considerable interest and indicates the skill of the authors in obtaining photographs with the concave form of Professor Rowland's gratings. For the determination of wave-lengths, a few details require attention which they do not mention in their paper. The method of working without a lens in front of the slit is liable to give rise to inaccuracies in the wave-lengths much greater than the limits of error assigned by them to their measurements. The authors have measured the lines of only a single metal, copper, and only a very small part of the spectrum of that element, namely, the region from wave-length 2369.9 to 1944.1. These facts alone render some of their conclusions open to criticism. I will very briefly touch upon these conclusions.

In the first place they state that "The difficulty in identifying lines and determining coincidences by employing the tables of metallic spectra in the ultra violet, published by the British Association, is illustrated by our work; for certain lines measured by Liveing and Dewar, which are identified by the committee with lines given by Hartley and Adeney, are in reality removed from each other, one or two lines intervening. In certain cases the lines of Liveing and Dewar are wholly beyond identification with those given by Hartley and Adeney."

For the purpose of identification I have always urged the publication of the photographs of spectra with the wave-lengths written over the lines, and the Royal Society possesses such a set of our spectra enlarged to three feet in length. When we found that our photographic enlargements would not be published we took the trouble to describe accurately the appearance of each one of the 3000 lines which we had measured, and we also quoted lineal measurements on the original photographs taken from prism spectra. We are thus able at any time to correct any measurements which may be erroneous or may have been erroneously quoted. That our spectrum of copper contains lines which are not easily identified with those of Liveing and Dewar is not difficult to account for, nor is it surprising that some of the lines are wholly beyond identification, for the following reasons:—(1). Liveing and Dewar's spectrum is from the arc, while our's is from sparks. (2). The measurements of Mr. Adeney and myself generally include all wave-lengths between 4725 and 2042.2. In the spectrum of copper our determination of *absolute wave-lengths* ceases at λ 2243.5, because above that point the lines were too feeble, unimportant, and ill-defined, and were therefore measured from prism photographs. This remark applies to a number of other lines lying between 2468.4 and 2277, which are indicated by italics in the *Phil. Trans.*, Part 1, 1884, p. 107. (3). All our measurements above 2329 are acknowledged by us to be so much less accurate than those in other portions of the spectra that they have been under revision during the last three years. For the practical purposes of chemical analysis they are accurate enough, and the lines are unimportant, but on theoretical grounds we have desired to obtain measurements of the most refrangible lines with the greatest accuracy possible and for every element. A little friendly correspondence with Professor Liveing and a comparison of our cadmium lines with those measured by Mr. Bell, the numbers for which were given in the *American Journal of Science* during last year, has shown that there is a remarkable agreement between our measurements when dealing with the same lines up to the

point above mentioned, but measurements of arc photographs cannot be compared with those from sparks.

The only conclusion that Messrs. Trowbridge and Sabine have arrived at which I can agree with is No. 4, "The limit of the copper lines is extended by our investigation."

No. 3 would bear modification; it stands thus—"Hypothesis in regard to coincidences of gaseous and metallic spectra cannot be safely based upon existing measurements of spectra in the ultra violet." This observation is not justified by photographs of only that portion of the spectrum of copper which was measured by Messrs. Trowbridge and Sabine, because it is here made to apply generally.

The most important part of Professor Grünwald's predicted and calculated spectra lie in a less refrangible region than the line 2320, that is to say where the measurements are more accurate. In conclusion I may add that Mr. Adeney is closely occupied on the most refrangible portion of the several ultra violet spectra which we have photographed, and early in the new year we hope to be in a position to publish something further on the subject.—I am, &c.,

W. N. HARTLEY.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 23, December 3, 1888.

The Preparation of Phosphoreous Strontium and Calcium Sulphides.—E. Becquerel.—The presence of very minute proportions of certain compounds in the preparation of the alkaline earthy sulphides is sufficient to modify the colour, the intensity, and duration of the light emitted. Thus, on preparing calcium sulphide by the recalcination of a mixture of oyster shells previously calcined along with sulphur, the addition of 1 to 2 per cent of manganese dioxide produces a mass having a fine yellow phosphorescence. Potassium persulphide, used in the same manner, causes the emission of a green light; with compounds of bismuth the light is blue and very persistent. Some of these additional substances, if used alone, produce no appreciable effect, and the joint presence of several of them is necessary.

The Black Waters of the Equatorial Regions.—A. Müntz and V. Marciano.—Certain affluents of the Orinoco and the Amazon have what is called black waters (*aguas negras*). When seen in mass they are of a coffee-brown or of a greenish black. In the shade they are almost black, but in a glass they are brownish yellow, though very transparent. They have no disagreeable taste and are preferred for drinking. The samples of these waters brought for analysis by V. Marciano are slightly acid, and contain, per litre, 0.028 gm. of humic compounds. There is no lime (less than 0.001 gm. per litre), nitrates are totally absent, and the total inorganic solids do not exceed 0.016 gm. per litre. They include silica, alumina, iron, and manganese oxides and potassa, with traces of ammonia. They do not undergo any chemical change on keeping.

Action of Carbon Disulphide on Clays; Production of Carbon Oxysulphide.—Armand Gautier.—The author fills a wide porcelain tube with china-clay previously ignited to nascent redness. The apparatus is placed in a good furnace, where it can be heated to white redness. The air is first expelled from the tube by a current of carbon dioxide and a current of the vapour of dry carbon disulphide is then passed over. The gaseous mixture issuing from the tube is composed of a trace of hydrogen sulphide, about 1 per cent of carbon dioxide,

60 to 64 per cent carbon oxysulphide, 35 to 39 per cent carbon monoxide, all mixed with vapours of sulpho-carbonic acid. The gas is richer in carbon monoxide if the temperature falls, but in oxysulphide if it rises. The clay is converted into aluminium sulphosilicate.

On Dioxethylic Acetone.—E. Grimaux and L. Lefèvre.—This paper is not well adapted for abstraction.

On Phthalimidine and Methyl Phthalimidine.—Phil. Barbier.—The composition of methyl-phthalimidine may be expressed by the formula C_9H_9NO .

MISCELLANEOUS.

Royal Institution of Great Britain.—The following are the arrangements for the Friday Evening Meetings before Easter, 1889:—

Jan. 25th. Professor G. H. Darwin, M.A., LL.D., F.R.S.—"Meteorites and the History of Stellar Systems."

Feb. 1st. Professor W. C. McIntosh, M.D., LL.D., F.R.S.—"The Life-History of a Marine Food-Fish."

Feb. 8th. Sir William Thomson, D.C.L., LL.D., F.R.S.—"Electrostatic Measurement."

Feb. 15th. Professor A. W. Rücker, M.A., F.R.S.—"Electrical Stress."

Feb. 22nd. Harold Crichton-Browne, F.R.G.S.—"In the Heart of the Atlas."

March 1st. Edmund Gosse, M.A., Clark Lecturer in English Literature at Trinity College, Cambridge.—"Leigh Hunt."

March 8th. Professor Oliver Lodge, LL.D., F.R.S.—"The Discharge of a Leyden Jar."

March 15th. Sir James N. Douglass, F.R.S., M.Inst.C.E.

March 22nd. Professor Edgar Crookshank, M.B.—"Microbes."

March 29th. A. Gordon Salamon, F.C.S., F.I.C.—"Yeast."

April 5th. The Rev. Canon Ainger, M.A.

April 12th. The Right Hon. Lord Rayleigh, M.A., D.C.L., LL.D., F.R.S.—"Iridescent Crystals."

NOTES AND QUERIES.

Science and Art Department.—According to the Science and Art Department students in organic chemistry will be required to analyse mixtures containing not more than two of the following acids (with mineral base or bases):—Salicylic, oxalic, formic, acetic, and tartaric. Can any of your readers give me a scheme for the work, or say where I will find a method? I know the reactions of the acids, but cannot construct a table.—STUDENT.

MEETINGS FOR THE WEEK.

THURSDAY, 27th.—Royal Institution, 3. "Clouds and Cloudland," by Professor Dewar, M.A., F.R.S.

FRIDAY, 28th.—Quekett Club, 8.

SATURDAY, 29th.—Royal Institution, 3. "Clouds and Cloudland," by Professor Dewar, M.A., F.R.S.

PATENTS, DESIGNS, & TRADE MARKS ACT, 1883.

In the matter of an application by RALPH WALDO EMERSON MACIVOR, of St. George's Club, Hanover Square, in the County of Middlesex, for Letters Patent for "Improvements in the production of white lead or carbonate of lead and the apparatus therefor," dated the 18th July, 1888, No. 10426.

NOTICE IS HEREBY GIVEN that the said R. W. E. MACIVOR has applied for leave to amend the Specification numbered as above.

A copy of the Specification in which the proposed amendments are shown can be inspected at the Patent Office; and particulars thereof were set forth in the Official Journal of the Patent Office issued on the 8th of December, 1888.

Any person intending to oppose the said application must leave notice of objection thereto (on Form G) at the Patent Office, 25, Southampton Buildings, London, W.C., within one Calendar month from the date hereof.

Dated this 8th day of December, 1888.

(Signed)

H. READER LACK, Comptroller-General.

WEGELIN AND HÜBNER, Halle-on-Saale, MACHINE WORKS AND IRON FOUNDRY.

Representatives: NICKELS & Co., 150, Holborn, London, E.C.

Dry Slide Air-Pumps.

E. Hübner's Patent, No. 37,746,
with increased effect through abolishing the noxious spaces; best
Air-Pump for Compression and Evacuation; useful effect up to 90
per cent with Steam power or driven by Belt.

Filter Presses and Monster Filter Presses,

with or without Washing Apparatus, with Heating Attachment,
with Attachment for Filtration with Exclusion of Air; in Wood,
Iron, or Bronze every desired size

Experimental Filter Presses

in Wood, Iron or Bronze.
Filtration Experiments, if desired, carefully conducted in
our Laboratory).

Steam Pumps & Transmission Pumps,
horizontal, vertical, mounted on column, Wall Pumps, Pumps for
Deep Wells, any size, for Water, Lyes, Saline and Muddy Liquids.
"Pump Cylinder in Iron or Bronze."

"Several Hundred different Patterns for Selection."

Membrane Pumps

worked by Steam, Transmission or Hand, in Iron, Bronze, or
Hard Lead, for raising Muddy, Sandy, Acid, or Saline Liquids,
any size desired.

Ice Machines.

Complete Freezing and Cooling Plant and Parts thereof,
i.e., Refrigerating-Worms, Ammonia-Pumps, Cocks, &c.
Also Small Ice Machines for Families, Laboratories,
Farms, Ships, &c.

Hydraulic Presses and Pumps.

Scum-Pumps

driven by Steam or Belt, with Automatic Regulation of Pressure,
or without same for feeding Filter Presses.

Steam Engines

with or without Cut-off Arrangement; with Rider Cut-off Com-
pound Steam Engines.
From 2—150 horse-power]

Steam Water Pumps,

newest, most approved Construction, taking up little room, and
especially suitable for placing in Wells, with great efficiency; up
to largest sizes.

Compressors driven by Steam or Belt,
for Liquefying Carbonic and Sulphurous Acids.

Extraction Apparatus,

for Extraction (cold or hot) with Benzol, Sulphuret of Carbon
Ether, Alcohol, Acetone, Water; in Iron or Copper. (Extraction
Experiments carefully conducted in our Laboratory if desired).

Laboratory Extraction Apparatus.

Montejus

in Cast or Wrought-iron, either lined with Lead or not.
Montejus for Sulphuric Acid, Mixing Vessels, Stills, Pans,
and Steam Boilers.

Complete Plant

for Chemical Manufactories, Colour Works, Glycerin
Refineries, Resin Distilleries, Paraffin Works, Tar Dis-
tilleries, Extract Works.

Price Lists, Drawings, Descriptions, and Highest
References for our above-named Specialities on
Application.

F. & M. LAUTENSCHLÄGER,
24, ZIEGEL STR.,
BERLIN N.

MANUFACTURERS AND CONSTRUCTORS OF CHEMICAL,
BACTERIOLOGICAL, TECHNICAL, AND MICROSCOPICAL
APPARATUS.

Large stock of Beakers, Gas-Burners of newest design, Evaporat-
ing Basins, Stands for Burettes, Water-baths, Balances of best
finish, Apparatus for Testing Human Food, &c., &c.

Gas Regulators for different temperatures ready filled for use.
Glass Jars for anatomical preparations, all sizes, and Bacteriological
Apparatus with latest improvements as a speciality.

We shall be glad to give estimates for new complete laboratories.

WHOLESALE—EXPORT.

SAMUEL HENSON,

Mineralogist, &c.,

LATE 277, STRAND,
97, REGENT STREET, LONDON, W.
Special Collections for Prospectors, Students, and Museums. Also
single specimens of Rare and Choice Minerals.

97, REGENT STREET,
(A few doors from St. James's Hall).

M. J. S. MERRY,
ASSAYER AND ANALYTICAL CHEMIST
SWANSEA.

Silicates of Soda and Potash in the state of
Soluble Glass, or in CONCENTRATED SOLUTION of first
quality, suited for the Manufacture of Soap and other purposes
supplied on best terms by W. GOSSAGE and Sons, Soap
Works, Widnes, Lancashire.
London Agents, COSTE and Co., 19 and 20, Water Lane, Tower
Street, E.C., who hold stock ready for delivery.

Water-Glass, or Soluble Silicates of Soda
and Potash, in large or small quantities, and either solid
or in solution, at ROBERT RUMNEY'S, Ardwick Chemical
Works, Manchester.

TO CHEMICAL MANUFACTURERS AND OTHERS.

TO LET.—Extensive Premises, situate
between Wrexham and Ruabon, on a branch of the Great
Western Railway, consisting of—

Large Shed, 167 feet long x 25 feet wide.
Buildings, 37 feet x 28 feet, 67 feet x 27 feet, and 25 feet x 20 feet.
Wharf, 500 feet long, with Railway Siding running the whole
length.

Within easy access, by rail, of several large Gas Works.

Apply to GEO. E. WOODFORD, RUABON.

THE CHEMICAL NEWS.

VOL. LVIII. No. 1518.

THE STANDARD OF ATOMIC WEIGHTS.

By BOHUSLAV BRAUNER, Ph.D., F.C.S.

I WISH to direct the attention of chemists to the numbers representing the atomic weights of our elements and to the basis which they are referred to.

Since the publication of Stas's classical researches (Part 2, 1865) two different bases were introduced, namely, (a) $H = 1.0025$, $O = 16$, and (b) $H = 1$, $O = 15.96$.

Two leading chemists have given in special articles (I do not mention treatises, &c.) preference to each of these bases.

Marignac (*Archives des Sci. Phys. et Nat.* (3), x., 3—6, 1883) prefers the system $O = 16$, $H = 1.0024$ for the following reasons:—

1. The atomic weights of all elements (except Al and Zn, see below) are determined either directly or indirectly with regard to oxygen, this being the only element whose relation to hydrogen has been determined directly. To assume hydrogen as the unit involves one error more for every atomic weight determination.

(Even in the case of such elements as Al and Zn, the atomic weights of which have been determined with direct reference to hydrogen, the weight of the latter has to be calculated from its volume, assuming that one litre of hydrogen weighs 0.08958 grm. This value, after application of the "Rayleigh correction," becomes 0.08988, or higher by 0.33 per cent, and the atomic weight of the element in question is lower by the same amount. So $Zn = 65.5$ becomes 65.3, and $Al = 27.0$ becomes 26.9.)

2. The relation of $H : O$ is difficult to determine, for this reason: it is likely to be altered by subsequent experiments (see below). This involves the alteration of all other atomic weights.

3. When $O = 16$, many atomic weights become whole numbers without becoming inexact, e.g., $C = 12$, &c., this being of advantage for the calculation of analyses.

4. The basis $O = 16$ may be accepted without Prout's hypothesis being regarded as true, for this value is just as arbitrary as $H = 1$ or $O = 1$ or $O = 100$.

Lothar Meyer and Seubert (*Berl. Ber.*, xviii., 1089—1097) bring forward several reasons for the basis $H = 1$, $O = 15.96$, and again $O = 16$, which later value, according to these chemists, seems to have been accepted chiefly from love for Prout's hypothesis. The reasoning of the said authors cannot be expressed in a few words. They admit that all atomic weights will have to be changed as soon as the ratio of oxygen to hydrogen is better determined, and they say they will be the first to re-calculate all atomic weights accordingly.

The time for such a re-calculation seems to have arrived now, several important researches having been published lately, the object of which is to fix the ratio $H : O$ more exactly. The values now obtained, together with the principal ones previously accepted, are given in the following list, the atomic weight of hydrogen being taken as unity, and the values for oxygen going from the highest to the lowest.

1. Scott, 1887 (*Proc. Roy. Soc.*, xlii., 396—400; *CHEM. NEWS*, lvi., 173—175), finds the composition of water by volume, $H = 1.994$, $O = 1$. When the density of oxygen referred to hydrogen is 15.9627, we get the ratio of atomic weights:—

$$H : O = 1 : 16.01 \dots (1).$$

2. Dumas, 1842, also Ostwald, 1884 (*Lehrb. der Allg. Chemie*), calculate from the composition of water by weight—

$$H : O = 1 : 16 \dots (2).$$

3. Clarke, 1882 (Recalculation, &c.), assumes, as most probable, the ratio—

$$H : O = 1 : 15.9633 \dots (3).$$

This, with Le Conte's correction (*loc. cit.*, p. 7) becomes—

$$H : O = 1 : 15.9622 \dots (3b).$$

4. Stas, 1865, L. Meyer and Seubert, 1883 (*Atomgewichte*, &c.)—

$$H : O = 1 : 15.96 \dots (4).$$

5. Van der Plaats, 1886 (*Ann. Chim. Phys.* (6), vii., 529) remarks, in a footnote:—"Par la détermination de l'eau qui est produite par l'oxydation d'un volume connu (15 litres) d'hydrogène, j'ai trouvé récemment pour ce rapport 15.94 à 15.96." This gives the ratio—

$$H : O = 1 : 15.95 \dots (5).$$

6. Keiser, 1888 (*American Chem. Journ.*, x., 249), obtained quite recently by the combustion of known quantities of hydrogen, weighed as palladium hydride, the ratio—

$$H : O = 1 : 15.9492 \dots (6).$$

7. Crafts, 1888 (*Comptes Rendus*, cvi., 1662), has determined experimentally the "Rayleigh correction," due to the compression of exhausted vessels used by Regnault for the density determinations, and, after its application to Regnault's experimental data, he calculates that the relative densities of hydrogen and oxygen are represented by the numbers—

$$H : O = 1 : 15.911 \dots (7).$$

This, calculated with Scott's ratio of volumes, 1.9965, gives the atomic weights—

$$H : O = 1 : 15.939 \dots (7a).$$

8. Lord Rayleigh, 1888 (*Proc. Roy. Soc.*, xliii., 356—363), calculates from the relative densities of hydrogen and oxygen with Scott's ratio, 1.9965, the following atomic weight.—

$$H : O = 1 : 15.912 \dots (8).$$

9. Stas, 1882 (*Mém. Roy. Ac. Belg.*, xl., 1—99), has determined the relation of silver to ammonium chloride and bromide volumetrically with a mathematical exactness never reached before, and finds the "molecular weight" of ammonium, $NH_4 = 18.078$ when $O = 16$. (This value has been calculated by Van der Plaats, instead of 18.076, as given by Stas himself). Unfortunately there exists an uncertainty whether, in the case of the synthesis of silver nitrate from the metal (Stas-Aronstein, p. 315), the dried or the fused silver nitrate corresponds to the formula $AgNO_3$, and so the atomic weight of nitrogen varies from 14.04 to 14.06, and of hydrogen consequently from 1.0095 to 1.0045. Assuming, however, that the dried silver nitrate contains a trace of water, and that the fused nitrate loses this water, together with a trace of nitric acid, so that the mean value corresponds to the formula $AgNO_3$, the atomic weight of nitrogen becomes $N = 14.049$, and consequently $H = 1.00725$.

But $1.00725 : 16 = 1 : 15.8848$. The result is the ratio—

$$H : O = 1 : 15.885 \dots (9).$$

10. Lord Rayleigh (*loc. cit.*) obtains from the relative densities of hydrogen and oxygen directly the following ratio—

$$H : O = 1 : 15.884 \dots (10).$$

11. Cooke and Richards, 1888 (*Am. Chem. Journ.*, x., 81—110, and 190—196). The weight of water formed from known quantities of hydrogen weighed in the gaseous state was determined. After application of the "Rayleigh

correction" to the result, obtained directly, viz., 15'953, the following ratio was found—

$$H : O = 1 : 15'869 \dots (11).$$

This is the lowest value of all, and it is not improbable that it is due to the unavoidable presence of a small quantity of nitrogen in the hydrogen used.

The following calculation shows the way in which the atomic weights of other elements are changed by changing the basis. As examples are taken the atomic weights of antimony (Cooke) and of uranium (Zimmermann), the one element standing in the middle and the other at the end of Mendeleeff's continuous series of elements:—

	O=	H=1. Sb=	U=
1.	16'01	119'99	239'76
2.	16	119'91	239'61
3.	15'9633	119'64	239'06
3b.	15'9622	119'63	239'04
4.	15'96	119'61	239'01
5.	15'95	119'54	238'86
6.	15'9492	119'53	238'85
7a.	15'939	119'45	238'70
8.	15'912	119'25	238'29
7.	15'911	119'24	238'28
9.	15'885	119'05	237'89
10.	15'884	119'04	237'87
11.	15'869	118'93	237'65

It is seen that in the case of antimony the variation represents *one unit*, with uranium more than *two units*, and generally no less than 0'00885, or nearly *one per cent* of the value of the atomic weight of every element.

Our atomic weights are regarded as "Constants of Nature." Their values may of course be found to vary slightly owing to fortuitous, errors incidental to their determinations, as in every human measurement.* This difference between the true numbers and the numbers found may, however, be lessened with every more exact determination.

But if we take hydrogen as a unit ($H=1$) the said "Constants" will be found to vary considerably, the basis ($H=1$) remaining constant, according to the possible variation of the "atomic weight" of oxygen from 15'869 to 16'01. Would it not then be paradoxical to call the atomic weights of elements under these conditions "Constants of Nature"?

Why should we make our atomic weights, dependent on the ratio of hydrogen to oxygen, a value which, besides changing from experiment to experiment, is the *most difficult* of all atomic ratios to determine accurately, its slightest variation causing *all* other atomic weights to vary the more the higher they are?

One way to get out of the difficulty would be to take oxygen as unity, viz., $O=1$ or $O=100$. This would, however, give numbers perfectly impracticable and absolutely impossible to remember.

Would it not be better to assume $O=16$ (without regarding Prout's hypothesis in its original rough form as correct) so as to make the atomic weights of all elements real "Constants of Nature" depending on a *constant basis*, and to change their values only when a more exact determination replaces a previous less exact one?

Bohemian University,
Prague, December 9, 1888.

* I do not mean the variation of atomic weights, already admitted by Cooke, Schützenberger, Butlerow, and to some degree by Crookes, which has been treated lately in a pamphlet by E. Vogel, M.D., of Alameda (San Francisco: The Bancroft Company, 1888), who, however, in some cases at least, seems to have overseen that the supposed variation falls within the limits of unavoidable experimental errors. With regard to that question the following passage in Mendeleeff's classical paper on the "Periodic Law" (1872) seems to me to deserve closer attention. "The weight is evidently due to a peculiar motion of matter, and there is no reason to deny the possibility of transformation of this motion into chemical energy or any other form of motion."

AN INVESTIGATION OF A CASE OF GRADUAL CHEMICAL CHANGE.*

By W. H. PENDLEBURY and M. SEWARD.

THE case of gradual chemical change with which the present investigation deals is that between hydrogen chloride and potassium chlorate, and also its action on a mixture of hydrogen chlorate and potassium chloride.

When dilute solutions of a chlorate (as for instance, potassium chlorate) and hydrogen chloride are mixed together, the liquid slowly acquires a chlorous smell, and there is a gradual liberation of oxidising material, chlorine, and oxides of chlorine. These immediate products cannot easily be investigated, for if the mixture is left to itself so that they accumulate in it, the gradual reaction first observed is stopped, and there ensues decomposition of the usual complex nature of these unstable solutions of chlorine and its oxygenated compounds.

But if a small quantity of potassium iodide is present it will be decomposed by these substances, and iodine will be gradually liberated as the final product of the reaction we have mentioned.

Now, Messrs. Harcourt and Esson, in their work on a gradual chemical change, measured the rate at which iodine was liberated in a liquid by ascertaining the time taken for a known quantity of sodium thiosulphate added to that liquid to be entirely decomposed. A small quantity of starch solution was added at the same time, and served as the signal of the presence of free iodine, which meant that the measured quantity of sodium thiosulphate was exhausted. The observation to be made was of the interval of time which elapsed between the addition of the thiosulphate and the first appearance of a blue starch colouration.

The same measurement and the same signal served our purpose. The first obvious difference between the two reactions is that, whereas in the former one (between hydrogen dioxide and hydrogen iodide) iodine was the primary result, in the later one it is a secondary result. This proved an unimportant difference. The secondary reaction between potassium iodide and the results of the first is, by comparison, instantaneous, not at all gradual. But another difference is of great importance. In their reaction the rate of decomposition became gradually slower, as one of the substances reacting continued to decrease sensibly in amount, and finally disappeared. In this reaction the amount of each substance decomposed bears an infinitely small ratio to the amount of each present; the composition of the mixture thus remains practically unchanged, and the rate of decomposition in each mixture is constant. Each experiment then is brought to an arbitrary close as soon as the constant velocity has been determined by the observation of a few intervals. The subjects of investigation were: the comparison of the velocities in different mixtures, and the establishment of laws connecting variation in velocity with variation of each of the ingredients.

In a large number of experiments hydrogen chlorate was used. Mixtures of dilute solutions of the two acids, chloric and hydrochloric, were made in various proportions, several series being taken, in each of which the amount of one of the acids present was varied in arithmetical progression, and the effect upon the rate investigated. Then the effect of the presence of certain quantities of potassium chloride upon the rate was observed, for the purpose of connection with a new series of experiments. In these potassium chlorate and hydrogen chloride were used, and series for variation of one of the ingredients taken as before. The effect of varying the quantity of potassium iodide present and that of varying the temperatures was also observed.

The results may be thus briefly summarised:—

Variation in Hydrogen Chlorate.—The rate varies with

* Abstract of a Paper read before the Royal Society, Dec. 13, 1888.

the amount of hydrogen chlorate, in the first place, directly, as the substance decomposed; and in the second place, with a small acceleration proportional to the quantity present, which thus has a coefficient of action independent of its being the substance decomposed. Thus—

$$R = aQ (1 + bQ),$$

where Q represents quantity, R rate, a and b constants.

Variation in Hydrogen Chloride.—The variation of the rate with that of hydrogen chloride is not of this simple nature. It would seem to be (1) an effect of the secondary order above mentioned (accelerative) on the decomposition of hydrogen chlorate by itself, and in addition to this (2) an effect of both primary and secondary order on the decomposition of hydrogen chlorate with hydrogen chloride.

Variation in Potassium Chloride.—The addition of this salt has a small accelerative effect on the normal rate proportional to its quantity. It thus appears to be a neutral salt not taking part in the reaction.

If a mixture of solutions of potassium chlorate and hydrogen chloride in proportion between 1 : 2 and 1 : 12 is made, complete double decomposition ensues; the hydrogen chlorate formed, in presence of the hydrogen chloride remaining, liberates oxidising material, and the potassium chloride formed exercises its specific influence on this reaction.

The secondary action upon potassium iodide producing iodine is practically an instantaneous one, unless the quantity of this substance is below a certain minimum. Below this the velocity observed in the mixture will be less than normal. The effect of increasing the amount of this substance to much greater than the minimum is closely analogous to that of a similar increase of any neutral salt.

The velocity is an exponential function of the temperature, as was observed in Messrs. Harcourt and Esson's investigations. As the latter increases in arithmetical progression, the former increases in geometrical progression. The rate is about doubled for a rise of 5° C. The ratio in this progression is not, however, absolutely constant, but varies a little with the temperature at which it is taken. Thus between 0° and 15° C. the rate is a little more than doubled for a rise of 5°; between 20° and 30° it is a little less than doubled.

POTASSIUM-CHLORATE.

By Dr. HODGKINSON, F.R.S.E., and F. K. LOWNDES.

IN a communication to the *CHEMICAL NEWS* (vol. lviii., p. 247) Mr. Warren drew attention to the so-called catalytic action of manganese on the decomposition of potassium chlorate by heat. It is very unlikely that any chemists really believe in such an action, although the term is still retained and used in a number of cases where the chemical action is obscure or has not been carefully investigated.

Without desiring to interfere with Mr. Warren's further prosecution of this subject, we venture to say that one of us made some experiments some years ago on this matter, and that we have repeated them lately in a slightly different manner.

Everybody knows the usual directions for making oxygen from potassium chlorate and manganese dioxide say, or imply, that the mixture shall not be too highly heated if pure chlorine-free gas is required.

If, instead of being careful in the heating, the chlorate be heated to complete fusion, and then a small quantity of manganese added, a sudden evolution of gas takes place, the particles of manganese "apparently" glowing as they come in contact with the chlorate. The oxygen contains more chlorine as the manganese is in finer powder and the purer it is. We have made some very

pure MnO₂ by precipitating permanganate with alcohol, and washing from the potash and igniting, and with this the glow on contact with the fused salt is most noticeable, and much chlorine is given off. At the same time some manganese evidently unites with potassium in some way, for the fused mass assumes a strong pink colour, and on dissolving in water a pink solution may be obtained which contains manganese. But much of this manganese compound appears to be decomposed on the addition of water to the fused mass. It should be noted that, after the addition of the manganese, the chlorate is heated to redness until no more oxygen is given off.

With other oxides various results are obtained; oxides of zinc, magnesia, bismuth, antimony, copper, and tin gave little or no result, neither hastening the rate of evolution of oxygen nor liberating chlorine when dropped on the fused chlorate. With cobalt, lead, and iron oxides and commercial HgO red. there is an immediate increase in the rate of evolution of oxygen and traces of chlorine come with it. With the yellow oxide of uranium, tungstic anhydride, and both the yellow and blue molybdic oxide, MoO₃, and with V₂O₅ there is an immediate increased evolution of oxygen with *very much* chlorine, so much so with WO₃ and MoO₃ that the test-tube appears quite yellow from the presence of the gas. With tungsten, molybdenum, vanadium, and phosphoric oxides and chlorate there is a soluble potassium salt formed, as one might expect; also, with uranium oxide, there appears to be some uranate formed.

Generally the action seems most energetic with the oxides of those elements capable of forming higher acid oxides or anhydrides. Some ammonium salts also give rise to an evolution of chlorine when dropped into fused chlorate, but this may, to some extent at least, depend on the nature of the acid of the salt. The activity of manganese may arise from the formation of a small quantity of a manganate or similar compound, and the decomposition and re-composition of this under the conditions.

Substances like platinum black or platinised asbestos, when dropped on to fused chlorate, certainly cause an evolution of gas without any chemical action taking place on themselves: but it is only a slight action, and ceases after a little time. It is the action of points only in facilitating the escape of gas.

DEFINITION OF CHEMICAL ATOMS.

By Professor A. GRÜNWALD.

A "CHEMICAL ATOM," in the author's investigations, is none of the metaphysical atoms hitherto admitted. The "chemical atom" of his theory is a complex of exceedingly many moveable particles, which are elastic, but so intimately connected together that no chemical process which comes under our consideration is capable of severing their union and breaking the atom into fragments. The author does not even conceive of the parts of the "atom" as absolutely immutable, any more than the atom itself, but as capable within finite limits of undergoing modifications, which have definite relations to their mutual reactions.

This view renders it perfectly intelligible that an "atom" may have a spectrum consisting of very numerous rays of different wave-lengths. This spectrum varies, according to fixed laws, when the chemical condition of the substance consisting of such atoms and its relations to other substances vary. It is not impossible, and even probable, that the particles of an atom are identical with the particles of the ether, or with condensation forms of the ether.

It will be easily seen that in an intimate union of two atoms, in which they combine each with one or with several adjacent particles, the latter, which possibly in the free condition of the atoms perform vibrations of

different periods, after the chemical combination of the atoms, vibrate in an accordant manner, and may thus become true moveable nodal points, or ramification points of the molecules of the compound in question. This will find its expression in the spectrum of the compound in such a manner that it will have rays belonging to each component. On the disruption of the compound they will generally be resolved into two rays of different periods, one of which belongs to the spectrum of one of the constituents now set free, and the other ray to the spectrum of the other constituent. In this connection Prof. Grünwald calls rays whose wave-lengths (within errors of observation) belong simultaneously to two or more groups of rays, which represent different components of a compound in the spectrum of the latter "empirical" nodal or ramification rays of the groups concerned. Such rays may be real nodes or ramification rays of the compound. Or they may be possibly double or plural rays, the wave-lengths of which coincide very closely, so that they cannot be distinguished with certainty within the limits of error. Nevertheless they are distinct, and belong to two or more non-identical rays of different groups.—*Proceedings of the Imperial Academy of Sciences of Vienna*, vol. xcvi.

ON THE RAPID DECOMPOSITION OF INSOLUBLE, NATURAL, AND ARTIFICIAL SILICATES FOR THE PURPOSE OF QUALITATIVE ANALYSIS.

By ALEXANDER JOHNSTONE, F.G.S.

Assistant to the Professor of Geology and Mineralogy in
Edinburgh University.

THE usual methods employed in the laboratory to bring about the decomposition of insoluble silicates for the purpose of qualitative (and quantitative) analysis, are in the author's opinion unsatisfactory, for the following among other reasons:—First, while most of the methods are fairly sure, all of them are *slow*; second, a few of the modes, besides being slow, are uncertain; and third, even after the necessarily long time wasted in the preliminary work of decomposition, *traces* of at least the important alkali, potash, and several other bases, such as berylla, &c., cannot generally be *satisfactorily* identified.

In view of the above objections, particularly that of the tardiness of the processes involved, the author was led to adopt, after very considerable modification, the method of heating with solid ammonium fluoride, which was, he believes, first proposed by Bunsen, but afterwards strangely neglected by him and his followers, and by the chemical fraternity generally.

The modified process of decomposition of silicates by means of ammonium fluoride referred to is briefly stated and explained below by the author, who has used it for the last year with unbroken success while assisting in the work of teaching the practical geology and mineralogy classes of the University of Edinburgh.

A small, thin, and roughly circular layer of solid ammonium fluoride is placed on the bottom of a clean platinum crucible or on a clean piece of platinum foil. A little—say as much as will lie on a threepenny-bit—of the finely-powdered mineral or artificial silicate is now placed on the top of the thin layer of ammonium fluoride so as to cover it completely. The platinum foil or crucible is now, by means of the ordinary mouth blowpipe, heated until most of the ammoniacal fumes have gone off. The hydrofluoric acid fumes, in passing through the layer of silicate above, promote its rapid decomposition. When the fumes have nearly ceased to come off, another portion—a mere pinch—of ammonium fluoride is added to the top* of the silicate layer and pressed down into it, and heat is applied again until, as before, the fumes have almost stopped coming off. This operation of adding a

mere pinch of ammonium fluoride and heating has to be repeated usually five or six times. When this has been done, and the whole process does not take up more than about eight minutes, the silicate will have been sufficiently decomposed to admit of the sure identification of the bases present.

The assay, after being heated strongly for an instant to drive off the last fumes completely, is now transferred to a small flask containing enough hydrochloric acid (about 40 p.c. solution) to cover it to the depth of about one inch. The acid liquid in which the assay is immersed is next evaporated rather more than one-third way down, and is then, after cooling a little, filtered off. The clear filtrate is now ready to be subjected to the ordinary methods of wet way examination for bases. Traces of lead, silver, and mercury may be found in the usual way in the undissolved assay residue. It is sometimes useful to examine also any flame colourations which this residue may give, by means of the spectroscope.

The author has by the above method found a ready and rapid means of distinguishing between the different species of felspar, mica, garnet, &c., &c.

Zircon (zirconium silicate), which is generally not well decomposed by other methods, undergoes complete, or almost complete, decomposition when treated *exactly* as stated above.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY
SAMPLES OF THE WATER SUPPLIED TO LONDON
FOR THE MONTH ENDING NOVEMBER 30TH, 1888.

By WILLIAM CROOKES, F.R.S.;

WILLIAM ODLING, M.B., F.R.S., F.R.C.P.,
Professor of Chemistry at the University of Oxford;

and C. MEYMOTT TIDY, M.B., F.C.S.,
Professor of Chemistry and of Forensic Medicine at the London
Hospital; Medical Officer of Health for Islington.

To GENERAL A. DE COURCY SCOTT, R.A.,
Water Examiner, Metropolis Water Act, 1871.

London, December 6th, 1888.

SIR,—We submit herewith the results of our analyses of the 182 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the seven London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from November 1st to November 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in a previous report.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 182 samples examined during the month, the whole were found clear, bright, and well filtered.

Despite the swollen and unfavourable state of the rivers during the past month, the condition of the water supply to the Metropolis, derived both from the Thames and the Lea, has continued excellent. It is the admitted character of river-derived water to vary in composition, although for the most part within a very small range, from week to week, and month to month; and although it is satisfactory to know that during times of heat and drought, when the maintenance of a high standard of excellence in drinking water is more especially called for, the state of

* It would be better of course if the ammonium fluoride were placed below the silicate, but this is often not very conveniently accomplished.

the river as a source of supply is at its best, it is hardly less satisfactory to observe, by means of adequate storage reservoirs and filter-beds, how slight, for the most part, is the influence, upon the water-supply, of the less favourable condition of the river prevailing in rainy seasons. Although somewhat reduced by the results recorded during the month of August, the mean standard of purity for the four preceding months was decidedly high; and notwithstanding the altered condition of the river during the past month, in only one particular do the results obtained differ appreciably from the mean results of the previous four months; and that particular, namely, the degree of freedom from colour-tint when subjected not to mere inspection, but to the exact determination afforded by the colorimeter, not one of any weighty significance. As regards the proportion of organic matter present as measured by the determination of the organic carbon, the mean result for the month furnished by the Thames-derived supplies, was 0.164 part of organic carbon in 100,000 parts of the water, as against a mean of 0.159 part for the previous four months; during which time, moreover, the maximum proportion met with during the past month, or 0.191 part in 100,000 parts of the water, was in several instances attained and exceeded. In the case of the East London Company's water derived from the Lea, the difference was in the same direction and to a similar insignificant extent, the mean amount of organic carbon for the month being 0.155 part in 100,000 parts of the water, as against a mean of 0.148 part for the previous four months.

We are, Sir,
Your obedient Servants,
WILLIAM CROOKES.
WILLIAM ODLING.

PHOTOGRAPHY OF THE LEAST REFRANGIBLE PORTION OF THE SOLAR SPECTRUM.*

By J. C. B. BURBANK.

It has been stated by eminent authorities, that the process of staining dry plates with various dyes is not applicable to the photography of the invisible rays beyond the red of the solar spectrum. To test this question I have undertaken a series of experiments with the dye cyanine. This dye has of late come into considerable prominence in photography, owing to its orthochromatic effect when mixed with other dyes, such as chinoline-red, azaline, erythrosine, and eosine.

It was discovered by Greville Williams, an Englishman, in 1861, but did not come into much prominence until the year 1884, when its usefulness as a sensitiser became more apparent. The dye is easily decomposed by light, and even in the dark both its solution and the plates coated with it are apt to become decomposed if kept for any length of time. Alone, it has been found very useful to sensitise plates for the orange and red portions of the spectrum. No experiments have to my knowledge been made upon the effect of heat rays upon cyanine plates.

The direct action of absorbents in the infra red has not, hitherto, been tried with any success; moreover, it has been stated by so eminent an authority as Captain W. De W. Abney that it was impossible to make plates sensitive to any rays below the A of the solar spectrum by means of the addition of dyes to a film. It is true, however, that Major Waterhouse has succeeded by means of turmeric in obtaining evidence of the existence of a few lines on the less refrangible side of A, but in all cases except one these were reversed.

The plates employed were made by the M. A. Seed Co.

of sensitometer 22. The method used in staining the plates and in the preparation of the dye is substantially the same as that employed by J. B. B. Wellington,* and is as follows:—

Fifteen grains of cyanine are gently heated (over a steam-bath) for from thirty to forty minutes in combination with 1 oz. of chloral hydrate and 4 ozs. of water. The whole mixture should now be stirred vigorously. While this operation is going on, 120 grains of sulphate of quinine are dissolved by heat in a few ounces of methylated spirit. (If methylated spirit cannot be obtained, a solution of 90 per cent alcohol and 10 per cent wood-spirits will answer perfectly well.) One ounce of strong aqua ammonia is now slowly added to the cyanine mixture above. Violent ebullition takes place immediately, chloroform being evolved, and cyanine is deposited in a soluble form on the sides of the vessel. The mixture is allowed to settle for a few minutes, and then the supernatant liquid is decanted off very slowly, care being taken not to detach any of the cyanine that is formed on the sides.

To the remaining cyanine, three or four ounces of methylated spirit are added to dissolve the cyanine; the quinine solution is then added; and to the whole more methylated spirit, until the whole mixture measures from eight to nine ounces. This solution constitutes the "stock" solution, and should be kept away from all light, as it is very apt to become decomposed.

All of the above operations should be conducted in as little light as possible; the following staining and drying processes should be conducted in absolute darkness.

To thirty ounces of water are added 1½ drachms of the cyanine stock solution; the graduate that contained the cyanine is now washed out, 1½ drachms of strong aqua ammonia are added, and the whole mixture is stirred vigorously. Into this bath two or three plates, or half a dozen strips, can be dipped at once. They should be left there about four minutes; meanwhile, the tray containing the plates should be rocked continuously, so as to ensure a uniform action of the dye.

This bath, after having been used once, should be thrown away, as the action on a second batch of plates would be weak and imperfect. The plates can now be drained, dried, and used. While developing, I was careful to exclude all light whatever, although I think it possible that the plates may be developed safely in a dark greenish yellow light. The developer used was a pyro, and potash developer of (generally) normal strength.

In the first experiments the spectrum was produced by a Rowland flat diffraction grating, mounted on a spectro-meter circle. This grating contained 17,000 lines to the inch. The observing telescope of the spectroscope was replaced by a camera and lens.

Certain photographs were also taken by means of a Rowland concave grating of 14,500 lines to the inch, and of 21 ft. 6 in. radius of curvature. With this grating, the amount of light being less and the dispersion greater than in the former cases, the exposure had to be increased.

In all of the experiments ruby-red glass screens were used in order to cut out all of the more refrangible part of the underlying spectrum. In some cases a weak solution of iodine in carbon disulphide was used with good effect.

No difficulty was found in photographing from the A line to wave-length 9900, or to the limit assigned by Abney as the limit of the diffraction spectrum. None of the lines were reversed. A special study of the A group was made, photographs being taken at different seasons in order to see if any changes in the remarkable group of lines constituting the A group could be noticed. No existing map represents this group correctly. Employing the second spectrum produced by a concave grating, 52 lines were observed between wave-lengths 7100 and 8000. In the same space Abney records only 24 lines. Between the head of A and the tail of A, the latter being the

* Contributions from the Jefferson Physical Laboratory.

* See "Anthony Photographic Bulletin," December 24, 1887.

single line before the series of doublets begin which is so characteristic of the A group, my photographs show 17 lines. These photographs were taken in June between ten and one o'clock.

These results are of special interest when we consider that Abney has said in a Bakerian Lecture, "As a result of these experiments I can confidently state that in no case did the addition of a dye cause any chemical effect to be produced by the rays below A of the solar spectrum, nor has Vogel claimed that they do."

It is interesting to note that Abney is led to believe that the photographic action, which has been noticed hitherto, by the use of dyes as sensitives, can be attributed to a certain action of nitrate of silver on organic matter. This effect is a bleaching one, and only the more fugitive dyes can produce it. We are led to conclude from Abney's paper, that he believes that only a chemical effect produced in a specially prepared emulsion can be used to reproduce the infra red rays. After many experiments he succeeded in producing such an emulsion. The colour of this verged upon the blue. Since the colour of plates stained with cyanine by the process I have described is also blue, there may be some physical significance in this resemblance.

My experiments show that a specially prepared emulsion is not necessary for the photography of the infra red region. The chemical theory advanced by Abney, therefore, seems to need revision.—*Proceedings of the American Academy of Arts and Sciences.*

ON THE FORMATION OF DEPOSITS OF OXIDES OF MANGANESE.*

By F. P. DUNNINGTON.

In explanation of the transfer of compounds of manganese, which has taken place in the formation of geological deposits, the only agency mentioned in works on chemical geology as taking prominent part is that of carbonated water, forming the soluble manganese bicarbonate. Dr. Bischof remarks†:—"With regard to the formation and alteration of manganese spar, the same relations obtain as in the case of iron spar." However, Fresenius has shown‡ that bicarbonate of iron and of manganese are obtained under different conditions. There is possibly a hint of the formation of manganese sulphate given by Karsten,§ but it is not definitely mentioned.

I propose in this article to call attention to the probability that manganese sulphate has taken a very important part in the formation of deposits of manganese ores.

Bunsen's analytic method for the valuation of manganese ores is based upon the fact that an acid solution of a ferrous salt will dissolve the higher oxides of manganese, with the formation of a corresponding amount of a ferric salt. Having observed the promptness with which such solutions are effected, I was led to make some examination of the action of similar solutions upon compact forms of oxide of manganese, and further, to ascertain some of the conditions under which solutions of ferrous sulphate, ferric sulphate, and manganese sulphate are decomposed. With this in view the following experiments were made:—

1. There was prepared a solution of ferrous sulphate and sulphuric acid in such proportions as would result from the oxidation of iron pyrites and solution in 25 parts of water. In 500 c.c. of this solution a lump of crystallised pyrolusite was suspended near the top of the liquid for forty-eight hours, resulting in dissolving a thickness of

0.804 m.m. (as calculated from the specific gravity of the mineral, area of the surface exposed, and loss of weight): a rate of solution equivalent to 6 inches in one year.

2. A lump of compact psilomelane was similarly suspended in the acid ferrous solution, and a thickness of 0.506 m.m. was dissolved in forty-eight hours, equivalent to 3.78 inches in one year. In each of the foregoing experiments a corresponding amount (45 and 12 per cent of the total) of the ferrous salt was converted to ferric.

3. A glass tube 3 c.m. in diameter and 20 c.m. in length, contracted at one end, was filled with a mixture of coarse powders of psilomelane, 75 grms., disintegrating pyrites (from Marienburg near Bonn), 100 grms., and glass. Through this tube two litres of water were allowed to percolate in the course of twenty-four hours, and in the liquid was found manganese sulphate, 7 grms., ferric sulphate, 1.45 grms., and sulphuric acid, 4.34 grms.

4. Through the above filled tube two litres more of water were similarly passed, and this dissolved of manganese sulphate, 0.154 gm., ferric sulphate, 0.07 gm.

5. Through the above filled tube two litres more of water were passed, while a continuous current of air was drawn through the tube; this dissolved of manganese sulphate, 0.292 gm., with about 0.07 gm. of ferric sulphate.

6. The glass tube was then re-filled, as at first, but using a bright granular pyrite (from Louisa Co., Va.). The current of air was kept up, and two litres of water, dropping at a uniform rate, were passed through the tube in the course of twenty-one days; this dissolved of manganese 0.098 gm. and no iron, while a small amount of ferric hydrate was formed and remained in the tube.

7. A neutral solution of ferrous sulphate digested cold with manganese carbonate, air being excluded, no change takes place; but when heated to 100° C. for two hours, considerable manganese sulphate and ferrous carbonate were formed.

8. Ferric sulphate solution reacts immediately upon manganese carbonate, forming manganese sulphate, ferric hydrate, and carbonic acid.

9. By reason of the fact, which is familiar, that ferrous sulphate solution is rapidly oxidised when exposed to the air, we find that when it is in contact with manganese carbonate, in the presence of air, the manganese carbonate is decomposed, forming manganese sulphate, &c., as above.

10. A neutral solution of ferrous sulphate with calcium carbonate, sealed in a tube under carbonic acid, was heated to 100° C. for two hours; mutual decomposition took place, forming ferrous carbonate and calcium sulphate.

11. Ferric sulphate solution reacts immediately upon calcium carbonate, forming calcium sulphate, ferric hydrate, and carbonic acid.

12. Ferric sulphate solution digested cold or hot with powdered manganese oxide was not altered.

13. Ferric sulphate solution was digested cold for nine days with sawdust and powdered psilomelane; considerable manganese sulphate was formed.

14. Manganese sulphate solution is not altered by exposure to air, but when so exposed, and also in contact with calcium carbonate, manganese oxide is gradually formed.

15. Manganese sulphate solution, digested cold with calcium carbonate in a sealed tube, is not altered; when heated, it is feebly affected, a little manganese carbonate being formed.

In view of the foregoing observations and results, it appears possible that many deposits of manganese in calciferous rocks owe their formation to the action of solutions of sulphates, and possibly an illustration of such action is presented in the manganese deposits of Crimora, Augusta Co., Va., which occur under the following conditions.

In the Shenandoah Valley, the upper portion of formation I. (Rogers) is composed of shales which are

* From the *American Journal of Science*, vol. xxxvi., Sept., 1888.

† "Chem. and Phys. Geol.," vol. i., p. 57, Trans. Cav. Soc.

‡ *Loc. cit.*, vol. iii., p. 531.

§ *Loc. cit.*, vol. i., p. 160.

well decomposed to a great depth, interspersed with remaining calciferous ledges, and as they pass westward these alternate with, and are succeeded by, ledges of siliceous limestone. In these decomposed shales, we find pure neutral iron ores, free from manganese, and associated with them there are manganiferous limonites and also psilomelane of high grade, frequently appearing to have grown in similar condition, and sometimes the same mass is composed in part of manganese and in part of limonite. South of the Potomac, no pyrites is visible in these shales, possibly owing to the great depth to which they have been decomposed; but at Harper's Ferry the iron ore lying in the same geological horizon has been worked down until compact pyrites has been reached. The presence of the pyrites in the latter renders it probable that it did exist extensively in the shales above described.

Assuming that pyrites did thus exist, generally distributed, we might expect a deposition of ores to have occurred in some such manner as the following.

Where pyrites has been deposited and subsequently has been exposed by reason of erosion, the outcrop is gradually converted into limonite by weathering, and the acid solution of ferrous sulphate, which sinks into the underlying deposits, must carry with it all manganese associated with the decomposing sulphide, also that in any disintegrating silicates and such as is distributed through the soil in the form of oxides or carbonate. As this solution is exposed to the air or meets with calcium carbonate, it will lose iron, the calcium carbonate removing all free acid, and an excess of the latter rock will remove all iron from the solution as ferrous carbonate, while the manganese sulphate would remain in solution until exposed to both air and calcium carbonate at the same time. Of course, the deposition of either iron or manganese oxides from solutions of sulphates by action of calcium carbonate results in the formation of calcium sulphate, which is carried away in solution in the water; so that the calcium is either wholly or in part removed from the strata in which such deposits are formed, and we would expect to find only occasional ledges remaining, as we find in the vicinity of the Crimora deposit.

An additional argument for the transportation of manganese as sulphate rather than bicarbonate lies in the great depth at which some deposits of manganese are found; for the bicarbonate would deposit oxide of manganese, wherever exposed to the air, while the sulphate would, where calcium carbonate had been previously removed, need to penetrate to a greater depth before reaching the conditions for its deposition. Moreover, the fact of the concentration of the manganese in masses rather than its general distribution through the decomposed shale would indicate that some condition additional to the exposure to oxygen had determined its deposition.

It is also to be noted that after all sulphur is removed from the overlying strata, the subsequent action of carbonated water might then occasion some transfer and redistribution of the previously formed deposits.

ON THE CIRCULAR POLARISATION OF CERTAIN TARTRATE SOLUTIONS.*

By J. H. LONG.

THE change in the circular polarisation of a solution of an active substance by admixture with an inactive one has been studied in several cases. Müntz found, for instance, that the specific rotation of cane-sugar for a concentration of 20 grms. in 100 c.c. changed from $[\alpha]_D = 66.5^\circ$ to $[\alpha]_D = 66.3^\circ$ by addition of 5 grms. of NaCl, and to 61.0° by addition of 20 m.grms.

The same chemist and others have shown the effects of adding various substances to sugar solutions. In most cases a decrease in the specific rotation was found.

Under certain circumstances the addition of an inorganic substance converts an inactive organic body into an active one, as in the case of mannite when in solution with alkalis, weak acids, and several neutral salts. Under still other circumstances the rotation of an active body can be very greatly increased by the addition of certain inactive ones, as is well illustrated by Gernez (*Berichte der Deutschen Chem. Gesell.*, xx., Ref. 251) in his experiments on mixtures of tartrates with molybdates, arsenates, tungstates, &c. He found, for instance, that the addition of NH_4MoO_4 to a solution of tartaric acid increased its rotation about fifty times.

This subject is one of great practical interest as well as of scientific importance, and it seemed to me that further investigation on the rotation of the tartrates must yield results of some value.

The following pages discuss results obtained with solutions of Rochelle salt in an investigation begun above a year ago, and which is still in progress.*

Apparatus and Methods.

In my experiments I employed a new model Laurent instrument made by Schmidt and Haensch, and used with this polarisation tubes 200 and 220 m.m. in length, surrounded by a water-jacket. The tubes were carefully measured and were found to differ so slightly from the given length (less than 0.05 m.m.) that I employ the whole numbers instead of introducing a fraction in the calculations. By means of suitable appliances the temperature of the solutions under examination was kept within 0.2° of 20° , as shown by a delicate thermometer. In most cases, however, this extreme accuracy in the control of the temperature was not necessary, as the variations caused by change of temperature were very small. In each test a dozen or more readings were made for each position of the analysing Nicol, and on the two verniers 180° apart. The instrumental error was almost inappreciable to begin with, and disappeared entirely by taking a mean of all the readings.

At a temperature of 20° a solution of tartaric acid containing 15 grms. in 100 c.c. showed a specific rotation $[\alpha]_D = 13.03^\circ$. This is diminished when the solution contains free mineral acids, and is also much diminished when certain neutral salts are added. With a solution containing 15 grms. of tartaric acid and 8 grms. of sodium chloride, I found the specific rotation less than one-half as much as before, viz., $[\alpha]_D = 6.16^\circ$.

If, instead of starting with tartaric acid, a neutral tartrate be taken and various salts added, quite different results are obtained. In the first place, the change in the specific rotation is much less than when the acid is used, and besides this the nature and amount of the change is characteristic of certain groups of salts. These points are shown below.

At the outset I prepared a quantity of pure Rochelle salt, sufficient for all experiments contemplated, and determined the rotation with five solutions containing exactly 5, 15, 25, 35, and 45 grms. in 100 c.c., measured at 20°C .

The results of these tests are given in the table, the specific rotation being calculated from the formula—

$$[\alpha] = \frac{10^\circ \alpha}{L \cdot C},$$

in which α is the observed angle of rotation, L the length of the tube containing the solution in m.m., and C the concentration of the solution, that is, the number of grms. in 100 c.c.

* This investigation was begun before the work of Gernez came to my notice, and before the publication of recent papers by Landolt (*Berichte*, 1888, p. 191), in which reference is made to the behaviour of certain tartrates. A second paper will deal with other tartrate solutions.

The specific rotation appears to be practically constant with the varying concentration, and the change in the angle of rotation by variation of temperature is inappreciable as I found by observing several of the solutions when heated to 35°. Krecke found (*Arch. Néerland.*, vii., 202), with a Rochelle salt solution containing 20 grms. in 100 c.c., the specific rotation $[\alpha]_D = 22.42^\circ$ at 25° C. For a solution containing 10.771 grms. of the anhydrous salt in 100 c.c., Landolt found (*Berichte*, vi., 1073) $[\alpha]_D = 29.67^\circ$, which is equivalent to 22.09° for the crystals.

This is practically the same as I obtained in the table above, and as I found it in numerous other tests carefully conducted I am inclined to think it is the true specific rotation. In what follows I will take 22.1° as the constant at 20°.

For each one of the following tests I took 20 grms. of the Rochelle salt and dissolved it in a narrow-necked flask graduated to hold 100 c.c. at 20°. Then the amount of the inactive salt was added and water enough to nearly reach the mark. After shaking, the flask was brought to the right temperature by suspending it in a large vessel of water kept at 20°. A little distilled water having the same temperature was added, and this was continued until, after shaking, the mark was just reached. The limit of error here is about one-twentieth of one per cent.

The solutions so made were then used in the polariscope. In all the experiments here given the temperature was kept at 20° and the 200 m.m. tube was employed.

The following table embraces the results obtained:—

Formula and amount of inactive salt added to 20 grms. of $\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$ in 100 c.c.	Observed rotation α .	Specific rotation $[\alpha]$.	Deviation from Normal.

A simple inspection of the table shows immediately several important points. The addition of the sodium salts without exception causes a decrease in the rotation, which is greater as the amount of inactive salt is increased. The behaviour of the thallium salt is interesting; here a remarkable change is produced. Experiments now in progress promise to throw some light on the action of thallium compounds in parallel cases. The addition of potassium and ammonium salts without exception increases the specific rotation. This deviation becomes greater as more of the inactive salt is added. We have here a remarkable difference between the sodium, thallium, and lithium compounds on the one hand, and the potassium and ammonium compounds on the other. These peculiarities may sometimes be applied in the quantitative analysis of salt mixtures. These characteristic points and the amount of variation can be most conveniently shown by curves in which the abscissæ are the amounts of inactive substance in solution with 20 grms. of Rochelle salt and the ordinates the specific rotation of the mixture, or better, the deviation of this from a simple water solution of the tartrate.

I have drawn curves on this plan. Some of them are practically straight lines which can be represented by a simple equation of the form $[\alpha] = (\alpha)_0 + Ag$, in which g is the amount of inactive substance in solution, and $(\alpha)_0$ the calculated rotation when $g=0$. It might appear that this value should be the same as that observed for the

pure tartrate solution, but I think that does not necessarily follow.

In the other cases the observations lead to a curve as expressed by $[\alpha] = (a)_0 + Ag + Bg^2$, in which the letters have the same meaning as before.

From the first three solutions containing potassium nitrate I have calculated according to this—

$$[\alpha] = 22.20^\circ + 0.048g + 0.0008g^2.$$

I have not thought it necessary to find an interpolation formula for all the solutions. It is evident that they intersect the base line at $g=0$ only in a few instances, and the deviations are usually greater than could be referred to errors of observation.

As mentioned above, the addition of a potassium salt increases the rotation, while sodium salts diminish it. The numbers as given seem to show no relation beyond this. However, if instead of giving the rotation for solutions containing equal weights of active and inactive substance they be calculated for equal numbers of molecules in solution, the results obtained show certain regularities which must be more than accidental. These desired values can be obtained readily and accurately by graphic interpolation, and in the following table they were so derived.

[α]. When for 1 molecule of tartrate 1, 2, or 3 molecules of inactive substance are present.

Formula of salt.	1 mol.	2 mols.	3 mols.
NaCl	21.86	21.41	20.99
NaBr	21.79	21.42	
NaNO ₃	21.68	21.41	21.16
Na ₂ SO ₄	21.32	20.49	
Na ₂ HPO ₄ .12H ₂ O ..	21.40

KI	22.63	23.09	
KNO ₃	22.60	23.07	
KSCy	22.52	22.66	22.82
KC ₂ H ₃ O ₂	22.60	22.87	23.25
K ₂ SO ₄	22.79		
NH ₄ Cl	22.54	22.67	22.81
NH ₄ Br	22.54	22.70	

(For $\frac{1}{2}$ mol.
= 21.61).
(For $\frac{1}{4}$ mol.
= 21.41).

We see from the above that the specific rotation in presence of two molecules of NaCl, NaBr, NaNO₃, or one molecule of Na₂HPO₄.12H₂O, or $\frac{1}{2}$ molecules of NaH₂PO₂.H₂O is very nearly the same, 21.41°.

In presence of one molecule of Na₂SO₄ it is a little less, while for NaC₂H₃O₂ and Na₂S₂O₃ no simple relation is apparent.

Two molecules of KBr, KCl, KI, KNO₃, and KC₂H₃O₂ exert nearly the same influence; one molecule of K₂SO₄ gives a smaller value, while KSCy is irregular.

Roughly, it appears that the potassium salt molecules increase the rotation in about the same proportion that the sodium salts diminish it. The explanation of this may not be immediately apparent.

Cases similar to those observed in the experiments of Gernez, referred to above, have been explained by the hypothesis of Biot according to which loose combinations are formed between the active and inactive substance having a rotation different from that of the former. Gernez has given the composition of some of these molecular combinations. The case in hand, however, is somewhat different. If we could assume here an action of mass by which on addition of potassium salts the solution would be made to contain neutral potassium tartrate, and on addition of sodium salts neutral sodium tartrate, then the disturbance could be partially explained. According to Landolt (*Ber.*, vi., 1073), the specific rotation of neutral

potassium tartrate, calculated as anhydrous, is 28.48, while that of the neutral sodium salt is 30.85. However, if instead of taking equal weights as our basis we take equal numbers of molecules, we obtain the following values representing the *molecular rotation* of the three salts—

$$\begin{aligned} K_2C_4H_4O_6 &= 64.42 \\ KNaC_4H_4O_6 &= 62.34 \\ Na_2C_4H_4O_6 &= 59.85 \end{aligned}$$

from which it is apparent that the conversion of 20 grms. of Rochelle salt into the neutral potassium tartrate would give a solution with increased rotation, while conversion into sodium tartrate would give a solution with diminished rotation. On this assumption the change can be accounted for in part, but only in part. Taking the rotation for the mixture of 20 grms. of KNaC₄H₄O₆.4H₂O with 20 grms. of KCl, given in the table above, we have $\alpha = 9.372^\circ$. Now, considering this as produced by 16.03 grms. of K₂C₄H₄O₆—the equivalent of 20 grms. of KNaC₄H₄O₆.4H₂O—we obtain a specific rotation—

$$[\alpha] = 29.23^\circ.$$

which is too much, Landolt's value being 28.48.

In the same way, taking the rotation $\alpha = 7.900^\circ$ found for the solution containing 20 grms. of KNaC₄H₄O₆.4H₂O and 20 grms. of NaCl and supposing this rotation produced by 13.76 grms. of Na₂C₄H₄O₆, we find the specific rotation

$$[\alpha] = 28.70,$$

which is too low, or, in other words, *too great a reduction*, Landolt's value being 30.85.

It will be seen, however, that the rotations found for the mixtures of the tartrate with the equivalent of two molecules of the simpler inactive salts give numbers which agree with Landolt's values. This is probably more than a mere coincidence. I am at present making a somewhat closer study of it.

The above mentioned hypothesis, while not adequate to explain fully the difference in behaviour between the inactive salts added to the tartrate, is still worthy of consideration, I think. In the further progress of the work I shall test it fully. The phenomenon is evidently a complex one, and the study of the behaviour of other double tartrates must be made before it can be thoroughly understood.

Preliminary experiments indicate that the double tartrates containing thallium or antimony will well repay investigation. The necessary material for such a study is now in course of preparation by an assistant in my laboratory, and with this I hope to be able to throw more light on the subject.

NOTICES OF BOOKS.

A Correlation Theory of Chemical Action and Affinity. By T. WRIGHT HALL, M.D. London: Remington and Co.

THAT a complete chemical theory capable of harmonising and interpreting the reactions which we encounter is still lacking must be conceded, though signs of a converging movement towards that goal are not wanting. Nor do we know that, however difficult, it would, as Dr. Hall thinks, be unpopular. We at least may venture to declare that any theory or instalment of a theory promising to solve the fundamental problems of the science will encounter at our hands, not the pillory, but a friendly greeting. But it must above all things be clearly intelligible. Neither the author of such theory nor any of his critics must be able to turn round and charge us with misinterpretation. Above all the new theory must legitimate itself by enabling us to understand and to predict phenomena. Dr. Hall's work seems to us deficient in

both these respects. The theory is nowhere stated plainly, and *totidem verbis* as a proposition to be proved, nor is it given in conclusion as an inference to be drawn. The reader may pick out a meaning—perhaps the right one—if he is able to understand every sentence of the book from beginning to end.

The author, in his preface and elsewhere, seeks to show a difference between the chemistry of our laboratories and the chemistry of the universe. He writes:—"The leading Themes in this Chemical Philosophy are—Gravity and Fire as Molecular Forces; and Matter's Form and Matter's Plasticity to those Forces. In our Chemical Philosophy, therefore, we do our little but our best to enthrone the cosmical, the enduring Chemistry of Nature, beside and above the local, the passing Chemistry of Art. In other words, I have tried to view Chemistry and its Forces and its Actions not only locally in piecemeals and in laboratories." Elsewhere he sneers at "the tiny Laboratories and the tinier Atoms and Molecules" as being insignificantly small and weak and as unfit to be the sole centre of chemical Phenomena and Thought."

But what evidence have we of the existence of two chemistries? What reason have we to suppose that, could we operate with quintillions of tons of matter instead of with milligrammes, we should meet with different reactions?

Dr. Hall seems to consider that solidity, not gaseity, is the original state of all matter, even of nitrogen and oxygen. He argues that "gaseity is given to air and most specially to the nitrogen air and to the oxygen air not only by heat but by very great heat force indeed, since very great cold is needed to cool these airs of their heat." Surely a strange reasoning!

On page 118 we read:—"The difference of charcoal from the diamond is so great that it warrants the assumption that charcoal would actually become sulphur if you changed its character befittingly." There is much virtue in an *if*. But, seriously speaking, let Dr. Hall once effect this transformation and we will proclaim him no sciolist, but the foremost chemist of the age!

Elsewhere we find cold spoken of as something other than a degree of heat, low in reference to our feelings or to our general experience. The author in this strain writes:—"The heat that is in oxygen will not burn man; the very great cold that is in carbon will not frostbite man."

Dr. Hall takes chemists to task for "speaking disrespectfully" of nitrogen as "azote," "chokestuff," a mere diluent of oxygen. But he must be aware that, save in these expressions, the value of nitrogen as one of the main essentials for the manifestation of life is fully admitted. We have heard it maintained that nitrogen had better be called "zote" than "azote."

We are told that certain "high-pitched cosmical spectral forces in Dayshine and Nightshine" are seen "unobtrusively gasifying and exploding daily and nightly billions of tons of nitrogen in our air." For this assertion we want evidence.

The moon is said (p. 284) to be "white hot."

We fear that Dr. Hall can scarcely be recognised as having contributed anything towards a theory of chemistry.

An Almanac for the Year of our Lord 1889. By JOSEPH WHITTAKER, F.S.A. Containing an Account of the Astronomical and other Phenomena, a Large Amount of Information respecting the Government, Finances, Population, Commerce, and General Statistics of the British Empire throughout the World, with some Notice of other Countries. London: 12, Warwick Lane.

It is a simple truism to say that Whittaker's Almanac still holds its pre-eminence. We have neither met with nor heard of any annual publication in any language which can hope to supersede it, or which does for any

other country the same service which it performs for the British Empire. It is a marvel how such an amount of information, so varied, so useful, and in general so accurate, can have been brought together and compressed into a single manageable volume.

The only section which seems to us in need of amendment is that relating to societies. Political leagues and philanthropic and moral associations are mixed up with the learned societies. It would, we think, be a convenience if each of these classes were placed separately. A number of societies are omitted, which we shall not mention, as to advertise them is by no means our business. We must, however, regret the provincial learned societies—some of which are of considerable importance—and the "Society for the Advancement of Medicine by Research" are not mentioned. In the case of two chartered societies, the Institute of Chemistry and the Entomological Society, the initials which Fellows subjoin to their names are not given, and those for the Linnean Society are said to be F.Z.S., instead of F.L.S.

We mention these little points, knowing that the Editors of "Whittaker" aim at absolute accuracy.

Taking the book as a whole, it is an essential requisite not merely for the "Editor's Table," but for the study of the savant and the author, and not less for the office of the man of business.

The Asclepiad: A Book of Original Research and Observation in the Science, Art, and Literature of Medicine, Preventive and Curative. No. 20, Vol. v. By B. W. RICHARDSON, M.D., F.R.S. London: Longmans, Green, and Co.

IN casting our eyes over this journal we notice an article which will doubtless excite the interest of our readers. It is an account of some carefully conducted experiments on the respirability of hydrogen gas, its action upon the animal organism, and its possible use as an anæsthetic and a hypnotic.

The two last points are effectually decided in the negative. Upon warm-blooded animals it has no anæsthetic or hypnotic action, but proves rapidly fatal. The fatal effect, according to the author, is due to the gaseous obstruction which it places in the way of the blood in the capillaries, as well as to the deprivation of oxygen. Hydrogen does not enter into any combination with the blood, but is held merely in mechanical suspension, from which it is easily dislodged on exposure to the air. In cold-blooded animals life is suspended for a long time before it is finally destroyed, and in insects there is merely a suspension of animation even after very prolonged immersion in the gas.

The remaining papers in the number before us cannot legitimately come under our notice. The "morphine habit" has doubtless its interest for the physician and the ethicist. The "Art of Embalming" has a value in case of specimens which it is desirable to preserve for future examination. If applied to the dead generally it is simply a crime—an attempt to interfere with the circulation of matter.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. Vol. cvii., No. 24, December 10, 1888.

The Use of Hydrogen Peroxide for Determining the Metals of the Iron Group: 1st. Chromium.—Adolphe Carnot.—Oxygenated water produces, in the

solutions of the metals of the iron group, reactions sometimes oxidising and sometimes reductive, which are capable of utilisation in chemical analysis. The author proposes to examine these in succession. Chromic acid yields, with oxygenated water, a very remarkable reaction, first observed by Barreswill. It is a blue colour produced on mixing the cold dilute solutions of the two substances. This reaction is characteristic as well for hydrogen peroxide as for the chromates, provided that there is added a very slight excess of a strong acid, so as to set the chromic acid at liberty. The colour is very fugitive; it scarcely lasts for a few minutes if the solution is nearly neutral, and for a few seconds if it contains more than one per cent of free hydrochloric or sulphuric acid. Barreswill, the first discoverer, ascribed this reaction to the formation of an instable action, but Moissan has shown that it is due to the combination of chromic acid and hydrogen peroxide. M. Carnot finds that when the oxygenated water has completed its action the chromic acid is entirely reduced to the state of chromium sesquioxide, whilst a corresponding quantity of the hydrogen peroxide has been decomposed. This reaction consequently furnishes a means for the volumetric determination either of hydrogen peroxide or of chromic acid. The best method of conducting the process is as follows:—The solution of the chromate to be examined is placed in a flat-bottomed flask and diluted with water, if needful, to the bulk of about 50 c.c., neutralising with ammonia or with hydrochloric or sulphuric acid, so as to leave only a very slight acidity. As reagent is taken the oxygenated water of commerce diluted with 5, 10, or 20 volumes of pure water. In this state it is very stable at common temperatures. It is dropped from a burette into the flask containing the solution of chromate, which should be supported above a sheet of white paper. The first drops produce in the yellow liquid a series of dark spots, which soon disappear. Then the liquid takes a blue colour, which disappears also on shaking the flask. Finally, it takes a green tint more or less intense according to the proportion of chrome. We cease as soon as a drop no longer produces a blue spot, and note the volume of the oxygenated water consumed up to this moment. We then operate in the same manner with a measured volume of a solution of pure potassium dichromate of known strength, and the comparison of the volumes used renders it easy to find the proportion of chromic acid in the first solution. In order that the phenomena may be the more easily comparable in the two experiments, it is well for the volumes of the solutions and the proportions of chromic acid not to differ too widely. The final colour should not be too dark.

NOTES AND QUERIES.

* * Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertising columns.

Science and Art Department.—(Reply to "Student.")—After separation of the inorganic bases as usual the organic acids mentioned may be detected as follows:—In the absence of carboic acid, the salicylic acid by the addition of Fe_2Cl_6 to neutral solution. Divide remainder of solution into two portions; distil one with dilute H_2SO_4 —formic and acetic acids pass over and are detected, the former by HgCl_2 and the latter by Fe_2Cl_6 . In remainder of solution the oxalic and tartaric acids, if present, are precipitated by CaCl_2 , the precipitate washed, and cold NaOH added; CaC_2O_4 dissolves and on boiling is reprecipitated. The CaC_2O_4 left on treatment with NaOH may be ignited to CaCO_3 and tested with HCl . Tables for the separation of organic acids will be found in "Jago's Chemistry," and "Jarmain's Qualitative Analysis."—W. E. YOULE.

Manufacture of Cupels.—In the Fifth Edition of "Mitchell's Manual of Assaying," p. 143, referring to cupels, is the following statement:—"It is very important that they should not contain carbon, and therefore, in making them, the bone-earth must not, as is sometimes recommended, be mixed with beer, or water containing adhesive substances. Nothing but pure water should be used," &c. For some months I have made a practice of mixing with the bone-ash several per cents of pure sugar or glucose, and when such cupels have been allowed to remain in the muffle thirty-five minutes before using, I have never been able to detect any ill effects from the practice. By this method, even when the best bone-ash is used, cupels much firmer and less liable to crack are produced, especially if it is desired to transport them or keep several barrels in stock. Will you please to state what the objection is to the practice, and greatly oblige one who is constantly receiving aid from the "Manual of Assaying," as well as your "Selected Methods of Chemical Analysis?"—Geo. A. MARSH, Assayer for Pennsylvania Lead Co., Mansfield Valley, Allegheny County, Penn., U.S.A., Nov. 19th, 1888.

MEETINGS FOR THE WEEK.

TUESDAY, Jan. 1st.—Pathological, 8.30. (Anniversary).
Royal Institution, 3. "Clouds and Clondland."
by Professor Dewar, M.A., F.R.S.
THURSDAY, 3rd.—Royal Institution, 3. "Clouds and Clondland,"
by Professor Dewar, M.A., F.R.S.
FRIDAY, 4th.—Geologists' Association, 8.
SATURDAY, 5th.—Royal Institution, 3. "Clouds and Clondland,"
by Professor Dewar, M.A., F.R.S.

SAMUEL HENSON,
Mineralogist, &c.,

LATE 277, STRAND,
97, REGENT STREET, LONDON, W.
Special Collections for Prospectors, Students, and Museums. Also single specimens of Rare and Choice Minerals.

97, REGENT STREET,
(A few doors from St. James's Hall).

ST. PAUL'S SCHOOL.—An Examination for filling up about Four Vacancies on the Foundation will be held on the 16th January next.—For information apply to the Bursar, St. Paul's School, West Kensington.

- Thomson, A., and T. Carnelley, solubility of isomeric organic compounds, 22
- Thudichum, Dr., alkaloids, 24
- Tibus, M., earrings, 257
- Tidy, C. M., poisons and poisoning, 33, 44
- W. Odling, and W. Crookes, London water supply, 46, 91, 176, 195, 252, 310
- Tiessier, J., analysis of a mixture of silver chloride, cyanide, &c., 232
- Tilden, W. A., address to Chemical Section of British Association, 123
- constitution of the terpenes and of benzene, 239
- Tin, 251
- alloys, determination of lead in, 109
- arsenic and antimony, separating, 96
- Tissue - printing, dyeing, and bleaching, improvements, 161
- Titanates, four new zinc, 108
- Tolane, hydration of, 24
- Toluensulphonic acids, formation of isomeric, 21
- Toluidines with phosphoric acid, behaviour of, 184
- Tolayl-propionic acid, synthetic formation of, 25
- Tomicek, F., and M. Brauner, action of sulphuretted hydrogen on arsenic acid, 203
- Tomlinson, C., bumping ebullition, 235
- Towns, sanitation of, 36
- "Townson and Mercer's Catalogue of Chemical and Physical Apparatus and Chemicals" (review), 292
- Toxicological detection of bromine and iodine, 203
- Trinity College, Dublin, 136
- Trowbridge, J., and W. C. Sabine, selective absorption of metals for ultra violet light, 216
- wave-lengths of metallic spectra in the ultra violet, 237, 247
- Tungsten compounds, action of ammonia on, 239
- Tuson, Prof. Richard Vine, Obituary, 230
- UEHLING, A.**, simplification of the calculation of analyses, 197
- Uffelmann, M., detection of fusel in spirits, 60
- Ulsch, K., drying apparatus, 207
- Kje dahl's determination of nitrogen, 49
- University College, 137
- Liverpool, 142
- Nottingham, 144
- presentation of portrait of Prof. Williamson, 302
- Universities and colleges, 135
- Urine, detection of aniline, 61
- of hydrogen sulphide in, 160
- of sugar in, 109
- determination of albumen, 245
- VAPOUR - DENSITIES**, new method of determining, 283
- tensions of alcoholic solutions, 132
- Veley, V. H., formation of oxygen, 260
- Venable, F. P., new test for iron, 178
- Vermillionette, 185
